## Foreword

Rocket propellants are hugely important members of the larger group of energetic materials. This continuously developing field requires knowledge and understanding of a wide-range of compounds from the highly reactive fluorine and nitrogen oxides, to organic alkylboranes and alcohols. For rocket propulsion, it is essential that accurate information on the physical and chemical properties of the chemicals involved has been determined precisely and can be relied upon. This is not only the case for known rocket propellants, but is equally essential for developing new, “greener” (less toxic) propellants for the future. The demands on rocket propellants are continuously developing and changing with time, as new needs and requirements for satellites and rockets emerge. Therefore, the *Encyclopedia of Rocket Propellants* is an essential resource for understanding current and past rocket propellants, as well as for designing those for the future. A collection of the vast physical and chemical data for past, present and modern rocket propellant systems has been missing, and it is essential that a source is available in which all reliable data has been collected together and presented in a clear and informative manner.

Amongst the many ways to categorize propellants for chemical rockets, they can be separated into two groups, namely, solid propellants or liquid propellants, with the former being subdivided into double-base or composite propellants. Liquid propellants can be subdivided into monopropellants or bipropellants, the latter of which can be again subdivided into hypergolic or nonhypergolic. Therefore, the complexity of these systems is self-evident. Hydrazine and the methylated derivatives methylhydrazine (MMH) and unsymmetrical dimethylhydrazine (UDMH) in combination with nitric acid or dinitrogen tetroxide are currently the most widely-used hypergolic propellants, however, hydrazine and its methylated derivatives are not only toxic, but also carcinogenic in test animals, and therefore it is of considerable importance to find less-toxic and non-carcinogenic alternatives which can still form hypergolic mixtures. Properties of many candidates in this context are summarized in this book. However, many more promising alternatives need to be found for the future. Despite the harmful properties of “traditional” rocket propellants such as MMH or UDMH, or the highly corrosive WFNA and RFNA, they continue to be used, while safer and more energetic alternatives are sought for the future.

Searching for new, environmentally friendly and/or increased performance rocket propellants requires knowledge of a large and diverse number of chemical compounds, many of which are not easy to handle. Despite this, since the publication of the book *Raketentreibstoffe* (Springer) in 1968 by the same author as this

encyclopedia, no other such comprehensive and detailed book has been published on rocket propellants making the *Encyclopedia of Rocket Propellants* a seminal work for past, present and future developments in this area.

Munich, Germany

# Preface

## Encyclopedia of Liquid Fuels

This is the second set of a series of sets in the *Encyclopedia of Rocket Propellants* summarizing the existing literature on rocket propellants, both liquid and solid rocket propellants. The first set, *Encyclopedia of Oxidizers*, published a few months ago, contains information on both liquid and solid oxidizers. This second set, *Encyclopedia of Liquid Fuels*, is a summary of literature on liquid fuels. The differentiation between liquid fuels and solid fuels was necessary because solid fuels usually are the binders for solid propellants, a topic reserved for a future, planned set in this series. The third set, *Encyclopedia of Monopropellants*, planned to be published next year, will be a very comprehensive summary of the chemistry of monopropellants. The fourth and fifth sets, planned for the coming years, will describe the performance of hypergolic and nonhypergolic bipropellant combinations, usually combinations of oxidizers and fuels. If time permits, future sets will eventually deal with various aspects of solid propellants, such as “Composite Solid Propellants” and “Double-Base Solid Propellants”, and they would also include gas generants which have found numerous industrial applications such as in airbag inflators in automobile passenger passive restraint systems. “Hybrid Propellants” may find a home in a future set in the distant future.

In spite of the increased capabilities of online search engines like Google Scholar, the current sets of books will be an indispensable tool for scientists and engineers in the rocket propulsion industry and research organizations. The hazards of working with rocket propellants need to be well understood.

Our *Encyclopedia of Rocket Propellants* book series will be the preferred reference source for future generations of rocket propellant chemists. When referring to the profession of rocket propellant chemists, this should not be done without quoting, tongue-in-cheek, the preface written by I. Asimov for J. D. Clark’s landmark book *Ignition!*:

“Now it is clear that anyone working with rocket fuels is outstandingly mad. I don’t mean garden-variety crazy or a merely raving lunatic. I mean a record-shattering exponent of far-out insanity.”

The reader will notice, though, that the correct terminology should have been “rocket propellants” and not just “rocket fuels”. The author of the current book feels that this quote from the literature adequately describes the risks involved for chemists involved with developing more energetic rocket propellants and explosives. The dividing line between powerful rocket propellants and potential explosives is very narrow and rocket propellant chemists are often treading on a narrow path. Nevertheless, or just because of the inherent risk, this is one of the most exciting branches of chem-

istry to be involved with. It is the chemistry of rocket propellants that has enabled the dramatic advances in space technology, with many benefits to the common consumer.

Reviewing the recent literature on rocket propellants and other energetic materials, one will notice that the increased capabilities of modern computers have enabled chemists to predict the performance of new molecules even before these compounds were ever made and tested in the laboratory. Numerous publications referenced in our books deal just with theoretical explorations of this type, and that is a difference to previous book publications on this subject.

Rocket propellants generally consist of oxidizers and fuels. The term “rocket fuels” is often misused to describe rocket propellants in general. Correct use of the term “rocket fuel” would only apply to the combustible, fuel-rich part of a propellant combination. Oxidizers are not rocket fuels. Oxidizers for liquid rocket propellants are generally subdivided by physical properties and/or by reactivity. So we differentiate between storable and non-storable (cryogenic) oxidizers. When looking at the reactivity of hypergolic combinations, it is more often the oxidizer and not the fuel that determines if the resulting combination is self-igniting on contact or not. Hypergolic oxidizers like fluorine or chlorine trifluoride will be hypergolic with most, but not all fuels. When listing combinations of rocket propellants, we always list the oxidizer first. This is because the properties and the activity of the oxidizer determine the nature of the combination more so than properties of the fuel would. There are fewer oxidizers than fuels in our inventory, so it is easier to organize book chapters on rocket propellant combinations first by arranging them by oxidizers and later by fuels.

A less frequently used term for propellant is *propellent*. When conducting literature searches, it may be advisable to search for both variations of the spelling.

### **About the Format of the Several Sets in the Encyclopedia of Rocket Propellants**

The manuscript for the *Encyclopedia of Rocket Propellants* has evolved through several iterations and modifications, and the terminology in designating sets, volumes, chapters, and sections has changed during this period. At one time *Encyclopedia of Oxidizers* was referred to as Volume 1 and *Encyclopedia of Liquid Fuels* was referred to as Volume 2, and so on. The most recent terminology is now referring to *Encyclopedia of Oxidizers* as a set of five volumes and similarly referring to *Encyclopedia of Liquid Fuels* as a set of five volumes. The sequence of volumes in a set and the sequence of chapters in a volume is arranged in alphabetical order, similar to a dictionary.

A critical reviewer might describe the format of the books as not much more than an annotated bibliography. The author is aware of the fact that collecting and reproducing references from the literature is not a very creative job (a librarian could do it), but to arrange these thousands of references in a systematic manner requires a good understanding of the subject matter.

Fifty years ago it used to be common practice to cite literature references followed by their Chemical Abstract citation. Providing the Chemical Abstracts citation often allowed the reader to read a more detailed abstract and to decide if it is worthwhile to obtain a complete copy of the original publication. Nowadays that function has been taken over by Digital Object Identifiers (DOI) in the Internet. Nevertheless, we have continued to carry along a few Chemical Abstract citations in addition to the DOI. Some of those citations are useful because they direct users to the Chemical Abstracts Registry Number which can then be used for subsequent, more specific searches in computerized data bases. Some of the books on energetic materials even contain an index of Chemical Abstract Registry Numbers. At the beginning of some sections, at the introduction of a new chemical name, usually several alternate names are listed. In those lists, the names bracketed by semicolons ; ; are the names used by Chemical Abstracts. That information is useful for literature searches in Chemical Abstracts.

### **Selection of Liquid Fuels**

When selecting combinations of bipropellants, hypergolic or nonhypergolic, it is usually the oxidizer that determines the reactivity of the combination once oxidizer and fuel meet in the rocket engine combustion chamber. The choice of oxidizers has less of an impact on the specific impulse than the choice of fuels with their widely varying hydrogen content. The selection of fuels, similar to the criteria for selection of oxidizers, is governed by a number of considerations:

- Specific impulse
- Reactivity with the intended oxidizer partner (hypergolic or nonhypergolic?)
- Boiling point/critical point temperature (storable at room temperature or cryogenic?)
- Storage stability
- Density (important for compact, pressure-fed systems)
- Corrosivity (corrosive oxidizers require exotic metals for tankage and tubing)
- Toxicity
- Availability
- Cost

Until the beginning of the Space Age, ethanol, gasoline, and kerosene had been used most extensively as rocket fuels, primarily because of low cost, room temperature storability, and relatively easy handling characteristics.

The world of liquid rocket fuels changed dramatically with the first use of liquid hydrogen, which performance-wise is the best and irreplaceable fuel. Liquid hydrogen was first used as the fuel in the second stage CENTAUR, but eventually its use expanded to first stages (boosters) as well, such as ENERGIYA, SPACE SHUTTLE, H-II,

DELTA-IV, ARIANE-V, and now the SPACE LAUNCH SYSTEM. A future hydrogen economy where not only rockets, but also automobiles and airplanes are powered by hydrogen, will benefit from the liquid hydrogen technology which was originally developed for rocket propulsion. Emissions from hydrogen-powered vehicles are clean and do not contribute to global warming. However, the current practice of making hydrogen by steam reforming of methane and water gas shift reaction will have to be replaced by other, cleaner methods, because it generates carbon dioxide as a by-product (although carbon dioxide from this process does not have to be released into the atmosphere. It can be collected and pumped underground).

Liquid hydrogen is a cryogenic fuel and not storable for a long time. Storable hypergolic fuels are still in use in a few satellite launch vehicles such as PROTON, the early versions of LONG MARCH, and GSLV/PSLV. Besides those booster stages, storable hypergolic fuels are mostly used for the uppermost stages of satellite launch vehicles, so-called “kick stages” because they have increased maneuverability compared to cryogenic upper stages and can deliver multiple satellites to different orbits and they can compensate for eventual inaccuracies of the lower stages.

Although the primary use of jet fuels is in air-breathing engines and not in rocket engines, descriptions of jet fuels and ramjet fuels were included in this book on rocket propellants. As it happened, jet fuels were often used as rocket fuels because they were readily available.

Ionic liquids were advertised as “green”, i.e. environmentally friendly rocket fuels. While it is true that due to their low vapor pressures they are safer to handle than most currently used fuels, their multi-step organic synthesis methods leave numerous hazardous by-products that need to be disposed of.

Today we are proud to herewith present to our readers the second increment of the *Encyclopedia of Rocket Propellants*.

# Contents

## Volume 1: Alcohols – Amides and Imides

### Alcohols — 1

- 1 Methanol — 2
- 2 Ethanol — 12
- 3 Isopropyl Alcohol — 33
- 4 Higher Alkanols ( $C_{n>3}$ ) — 36
- 5 Polyols — 44
- 6 Other Alcohols — 45
- 7 Alcohols with Substituents in the Alkyl Group — 45
- References — 45

### Aliphatic Amines — 55

- 1 Aliphatic Amines — 55
- 2 Aliphatic Amines with One Nitrogen Atom in the Molecule — 74
- 3 Ethylamines — 104
- 4 Propylamines — 113
- 5 Amines with Large Alkyl Groups — 114
- 6 Imines with One Nitrogen Atom — 116
- 7 Saturated Open-Chain Aliphatic Amines with More than One Nitrogen Atom in the Molecule — 116
- 8  $C_3$  and  $C_4$  Di- and Triamines — 126
- 9 Cycloaliphatic Amines — 139
- 10 Other Open-Chain Aliphatic Amines with More than One Nitrogen Atom in the Molecule — 145
- 11 Cycloaliphatic Secondary Aliphatic Amines with More than One Nitrogen Atom in the Molecule — 147
- 12 Tertiary Aliphatic Amines with More than One Nitrogen Atom in the Molecule — 147
- 13  $C_{\geq 6}$  Non-Cyclic Multifunctional Amines — 152
- 14  $C_7$  Multifunctional Amines — 153
- 15  $C_8$  Multifunctional Amines — 153
- 16  $C_{10}$  Multifunctional Amines — 153
- 17 Other Tertiary Amines — 153
- 18 Unsaturated Aliphatic Amines — 154
- 19 Azido-Substituted Amines — 156
- 20 C-Nitro- and C-Nitroxy-substituted Alkylamines — 174
- 21 C-Cyano-Substituted Amines — 178

- 22 Hydrazido-Substituted Amines — **179**
- 23 C-Hydroxy-Substituted Amines — **179**
- 24 Dimethylaminoethanol — **191**
- 25 Nitrate Esters of Hydroxyethylamines — **193**
- References — **194**

**Alkanes — 221**

- 1 Alkanes — **221**
- 2 Methane — **232**
- 3 Ethane — **287**
- 4 Propane — **295**
- 5 Butane and Pentane — **311**
- Higher (C>5) Aliphatic Hydrocarbons — **311**
- 6 Hexane — **311**
- 7 Heptane — **313**
- 8 Octane — **317**
- 9 Decane — **318**
- 10 *n*-Dodecane — **323**
- 11 Hexadecane — **337**
- 12 Branched Chain Aliphatic Hydrocarbons — **339**
- References — **340**

**Alkenes and Alkynes — 367**

- 1 Unsaturated Hydrocarbons: Alkenes and Dienes — **367**
- 2 Ethene (Ethylene) — **368**
- 3 Propene (Propylene) — **374**
- 4 Acetylene and Acetylene Derivatives — **375**
- References — **391**

**Alkylboranes — 397**

- 1 Alkylboranes — **397**
- 2 Trialkylboranes — **398**
- 3 Alkyldiboranes — **407**
- 4 Alkylpentaboranes — **410**
- 5 Alkyldecaboranes — **419**
- 6 Other Boron-Containing Organic Compounds — **423**
- 7 Boron-Containing Polymers — **424**

# Alcohols

## Alcohols

This chapter contains sections on alkyl alcohols (alkanols) used as rocket fuels. Looking at the structural formulas of hydrocarbons and alcohols, the simplest alcohols are derived from alkanes by replacing one hydrogen atom by a hydroxyl group (or – in theory, but not in reality – by inserting an oxygen atom between a carbon atom and its hydrogen neighbor). In the case of methane, the resulting alcohol would be methanol. A synonym for alkyl alcohols is alkanols. As most rocket propellant chemists know, inserting oxygen into a fuel molecule is not a good idea if you want to obtain a high-energy fuel. It shifts the oxygen balance of the molecule closer to that of carbon dioxide, the typical combustion product of all hydrocarbons and alcohols, and makes the molecule a less valuable fuel. The main reason that alcohols are used instead of hydrocarbons as rocket propellants is that they have higher boiling points than the hydrocarbons with the same number of carbon atoms from which they are derived, and thus they can be handled as liquids instead of cryogenics at room temperature. The lower ( $C_1$  to  $C_4$ ) alcohols are miscible with water in all proportions and, if accidentally spilt, are easier to clean up than hydrocarbons. Alcohols are widely used as cleaning solvents and disinfecting wipes in the aerospace industry. Alcohols are good solvents. Alcohols can serve as solvents for additives that make them hypergolic with hydrogen peroxide or nitric acid.

Fuels that contain some oxygen are more easily tolerated and show less of a performance loss if the oxidizer in a rocket engine is fluorine instead of oxygen. As will be shown, kerosene gives better performance with a mixture of fluorine and oxygen (FLOX) than with either oxidizer by itself. This is because, in an equilibrium mixture of combustion products, carbon goes preferentially with oxygen and hydrogen goes preferentially with fluorine to achieve the equilibrium mixture in the rocket exhaust. Thus, if one plans on using fluorine, instead of physically adding oxygen to the oxidizer ( $F_2$ ), one might as well introduce it with the fuel.

The main alkanol used as a rocket propellant is (was) ethanol. The other saturated alkyl alcohols have not achieved any significance as rocket propellants. Compilations of the physical and thermodynamic properties of alcohols are available in [1, 2].

Another family of fuels that are closely related to alcohols are the ethers. Ethers are derived by combining two alkyl groups with an  $-O-$  bridge or by dehydrating two moles of an alcohol through the removal of one mole of water. The oxygen balance of ethers is more negative than that of alcohols, so they should make better fuels. Ethers are only partially miscible with water. Ethers have been tested as rocket propellants but do not offer any advantages over alcohols. Ethers will be described in a separate chapter, “Ethers,” in *Encyclopedia of Liquid Fuels*.

## 1 Methanol

Methanol (methyl alcohol,  $\text{CH}_3\text{OH}$ , CAS RN [67-56-1]) has only very rarely been used as a rocket fuel by itself. Some of the early experimenters in the founding days of JPL and Aerojet used methanol instead of ethanol because its lower combustion chamber temperature was more manageable than that of pure ethanol. Its heat of combustion and performance as a rocket fuel are inferior to those of ethanol. When, in the past, rocket engine designers chose methanol over ethanol, it was most likely because they wanted lower exhaust temperatures or they could not handle the higher rates of heat transfer from LOX/EtOH combustion at the interface between the combustion chamber and the coolant jacket. Methanol was the main constituent of a fuel blend called “C-Stoff,” which consisted of 57 mass-% methanol ( $\text{CH}_3\text{OH}$ ), 30 mass-% hydrazine hydrate ( $\text{N}_2\text{H}_5\text{OH}$ ), and 13 mass-% water with a few percent of potassium cyanoferrate(III) dissolved as a catalyst and was used with hydrogen peroxide as the oxidizer in a bipropellant rocket engine in the German interceptor rocket plane Me-163B during WWII. So, the history of the use of methanol as a rocket propellant actually started very early.

### 1.1 Production and Availability of Methanol

Methanol is made by reacting synthesis gas over a catalyst. Synthesis gas (“syngas”) is made from natural gas by steam reforming:

As long as natural gas is readily available, methanol will be readily available, too. The conversion of methane directly into methanol by partial oxidation has been attempted. This would be a useful method of capturing methane at remote petroleum well heads that would otherwise be flared off. The multi-step conversion of natural gas to methanol is already used as a means of transporting hydrocarbon fuels from one place to another. Methanol is easier to transport than liquefied natural gas (LNG). At its point of use, methanol is converted back to synthesis gas and other products – predominantly ethylene for polyethylene synthesis. Methanol can also be made from syngas by coal gasification or the conversion of cellulosic waste.

In the distant future, if the world gets serious about reducing the amount of  $\text{CO}_2$  emissions to curb global warming,  $\text{CO}_2$  captured from stationary emission sources could be converted to methanol (assuming the ready availability of hydrogen or electric power) and thus diverted, and the carbon could be recycled for a useful purpose. Methanol from  $\text{CO}_2$  would also be the fuel of choice for an in-situ resource utilization (ISRU) fuel production facility on the surface of Mars, where the atmosphere consists

mostly of carbon dioxide, and carbon dioxide forms part of the white polar caps that can be seen with even a cheap telescope. Methanol for ISRU would be easier to store than liquid methane.

## 1.2 Physical Properties of Methanol

Physical properties of methanol are summarized in Table 1.

**Table 1:** Physical properties of methanol.

| Property                                 | SI units                   | Other units        | References |
|------------------------------------------|----------------------------|--------------------|------------|
| Molecular mass                           | 32.0419 g/mol              | 31.209 mol/kg      | [3]        |
| Freezing point                           | $176 \pm 1$ K              | $-97 \pm 1$ °C     | [3]        |
| Boiling point                            | $337.8 \pm 0.3$ K          | $+64.7 \pm 0.3$ °C | [3]        |
| Density at 293 K                         | $0.7914$ g/cm <sup>3</sup> | —                  | [4]        |
| Critical temperature                     | $513 \pm 1$ K              | $240 \pm 1$ °C     | [3]        |
| Critical pressure                        | $8.1 \pm 0.1$ MPa          | 80.2 atm           | [3]        |
| Critical density                         | $8.51 \pm 0.07$ mol/L      | —                  | [3]        |
| Refractive index ( $n_D$ ) <sup>20</sup> | 1.3288                     | —                  | [4]        |

The velocity of sound in methanol was measured by a single-pulse technique for temperatures from 294 to 366 K (70–200 °F) and for pressures from 0.1 to 4 MPa (1–40 atm) [5].

### 1.2.1 Density of Methanol

The saturated liquid density of methanol for the range 175.5–512.5 K (–97.6 to +239.4 °C) can be calculated from the equation

$$\rho = A \times B^{-[1 - (T/T_c)]^{\frac{2}{7}}}$$

where  $\rho$  is the density in g/cm<sup>3</sup>, A and B are correlational constants (A = 0.2928, B = 0.2760),  $T_c$  is the critical temperature (512.5 K), and  $T$  is the temperature in kelvin [6].

The densities of methanol and ethanol are shown in Figure 2, which is in the following section on ethanol.

### 1.2.2 Vapor Pressure of Methanol

The vapor pressure of methanol can be calculated using an Antoine-type equation:

$$\log_{10} P = A - [B/(T + C)],$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. The constants  $A$ ,  $B$ , and  $C$  are listed in Table 2 for three different temperature ranges, and the top two sets of data were used to create a vapor pressure curve as shown in Figure 3, together with vapor pressure data for ethanol. That figure is shown in the following section about ethanol.

**Table 2:** Vapor pressure coefficients for methanol.

| Temperature range, K | A       | B        | C       | References |
|----------------------|---------|----------|---------|------------|
| 353.5–512.63         | 5.15853 | 1569.613 | –34.846 | [7]        |
| 288.1–356.83         | 5.20409 | 1581.341 | –33.50  | [8]        |
| 353–483              | 5.31301 | 1676.569 | –21.728 | [9]        |

Note: Coefficients were calculated by NIST from the author's data

Another vapor pressure equation for the range 206–513 K (–67 to +240 °C) uses five coefficients:

$$\log p_V = A + \frac{B}{T} + C \log T + DT + ET^2$$

where  $p_V$  is the vapor pressure in mmHg and  $T$  is the temperature in kelvin. The correlation constants are  $A = -42.629$ ,  $B = -1186.2$ ,  $C = 23.279$ ,  $D = -35.082 \times 10^{-3}$ , and  $E = 17.578 \times 10^{-6}$ . For a temperature of 298 K, this equation gives a vapor pressure of 124 mmHg [10].

### 1.2.3 Viscosity of Methanol

Viscosity data for methanol and several higher alcohols were obtained in the temperature range 208–373 K (–65 to +100 °C) using an Ubbelohde viscometer [11] The results were compared with existing data, and all the data were fitted to the Fulcher (Tammann-Hesse) equation by the method of least squares. The implication of the values of  $T_0$  in this equation for these and other associated liquids was critically reviewed, and an attempt was made to interpret the significance of  $T_0$ . The quantity  $T_0$  (written as  $-C$  by some authors) was found to be largest for those liquids in which very extensive hydrogen bonding is possible. The viscosity data can be expressed by a Fulcher-type equation:

$$\log \eta = A + B/(T - T_0)$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The constants  $A$ ,  $B$ , and  $T_0$  for methanol and ethanol are summarized and compared to those of other

**Table 3:** Constants and valid ranges for the Fulcher viscosity equations.

|                    | A       | B        | $T_0$   | Viscosity at<br>298 K, cPs | % Error | Valid range, °C |
|--------------------|---------|----------|---------|----------------------------|---------|-----------------|
| Methanol           | -1.6807 | 354.876  | 48.585  | 0.55                       | 2.05    | -98.3 to +50    |
| Water              | -1.5668 | 230.298  | 146.797 | 0.90                       | 0.51    | -10 to +160     |

Data source: [11]

associated (hydrogen-bonded) liquids in Table 3. In the case of methanol, the equation would be

$$\log \eta = -1.6807 + 354.876/(T - 48.585)$$

At 298 K, this equation yields a viscosity of 0.55 cPs for methanol with a  $\pm 2\%$  error.

The dynamic viscosity of liquid methanol in the range 273–323 K can be calculated from the following equation:

$$\eta = 1.107 \times 10^{10} T^{-4.163}$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The viscosity at 298 K is 0.547 cPs [12].

The dynamic viscosity of liquid methanol in the range 175–512 K (-97 to +239 °C) can be calculated from the following equation:

$$\log \eta = A + \frac{B}{T} + CT + DT^2$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The coefficients for this equation are available for two different temperature ranges, as listed in Table 4.

For example, the viscosity from this equation at 298 K is 0.53 cPs.

**Table 4:** Viscosity correlation coefficients for liquid methanol.

| Temperature range, K | A      | B     | $C \times 10^2$ | $D \times 10^6$ |
|----------------------|--------|-------|-----------------|-----------------|
| 175.5–233            | -99.73 | 7.317 | 46.81           | -745.3          |
| 233–512.5            | -17.09 | 2.096 | 4.738           | -48.93          |

Data source: [10]

### 1.2.4 Surface Tension of Methanol

Once the surface tension at one temperature  $T_1$  is known, the surface tension at other temperatures can be calculated by the Othmer relation. The surface tensions of methanol and other liquids can be calculated from the following equation:

$$\sigma = \sigma_1 [(T_c - T)/(T_c - T_1)]^{\frac{11}{9}}$$

where  $\sigma$  is the surface tension in dyn/cm,  $T_c$  is the critical temperature (513 K), and  $T$  is the temperature in kelvin. A similar equation that applies to the range 175.5–512.5 K (–97.6 to +239.4 °C) uses an exponent of  $n = 0.8115$  instead of 11/9 [6]. Data for the surface tension of methanol are summarized in Table 5.

**Table 5:** Surface tension of methanol.

| Temperature |    | Surface tension |              | References |
|-------------|----|-----------------|--------------|------------|
| K           | °C | SI units        | Other units  |            |
| 293         | 20 | 22.5 mN/m       | 22.5 dyn/cm  | [13]       |
| 298         | 25 | 21.88 mN/m      | 21.88 dyn/cm |            |
| 293         | 20 | 22.6 mN/m       | 22.6 dyn/cm  | Unknown    |
| 293         | 20 | 22.56 mN/m      | 22.56 dyn/cm | [14]       |
| 313         | 40 | 20.96 mN/m      | 20.96 dyn/cm |            |
| 333         | 60 | 19.41 mN/m      | 19.41 dyn/cm |            |

### 1.2.5 Thermal Conductivity of Methanol

The thermal conductivity of methanol as a saturated liquid can be calculated from the equation

$$\lambda = A + BT + CT^2$$

where  $\lambda$  is the thermal conductivity in  $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The correlation constants for methanol in the temperature range 175–483 K (–98 to +210 °C) are  $A = 770.13$ ,  $B = -114.28 \times 10^{-2}$ , and  $C = 2.79 \times 10^{-4}$  [6]. At 293 K (+20 °C), the thermal conductivity of methanol is  $0.192 \text{ W m}^{-1} \text{K}^{-1} = 459.2 \mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1} = 0.4592 \text{ mcal s}^{-1} \text{cm}^{-1} \text{°C}^{-1} = 0.0004592 \text{ cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$ .

The thermal conductivity of methanol vapor can be calculated from the polynomial equation

$$\lambda_G = A + BT + CT^2 + DT^3$$

where  $\lambda_G$  is the thermal conductivity of methanol vapor at low pressure (approx. atmospheric pressure) in  $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The correlation constants for methanol in the temperature range 273–1273 K (0–1000 °C) are

identical to those of ethanol (namely  $A = -18.62$ ,  $B = 9.95 \times 10^{-2}$ ,  $C = 2.90 \times 10^{-4}$ , and  $D = -12.38$ ) [10]. See also [15].

### 1.2.6 Heat Transfer Coefficient of Methanol

Based on measurements in a thermosyphon heat pipe at heat flux conditions of  $7.35 \text{ kW/m}^2$ , the overall heat transfer coefficient of methanol was  $0.126 \text{ kW m}^{-2} \text{ }^\circ\text{C}^{-1}$  and the overall heat transfer coefficient of ethanol was  $0.17 \text{ kW m}^{-2} \text{ }^\circ\text{C}^{-1}$  (that of water is  $0.16 \text{ kW m}^{-2} \text{ }^\circ\text{C}^{-1}$ ) [16]. In a vertical pipe, the heat transfer coefficients were  $750$  and  $627 \text{ W m}^{-2} \text{ K}^{-1}$  for ethanol and methanol, respectively [17].

### 1.2.7 Thermodynamic and Thermal Properties of Methanol

#### 1.2.7.1 Heat Capacity of Methanol

The heat capacity of methanol vapor assuming ideal gas behavior can be calculated from the polynomial equation

$$C_p = 21.137 + 7.0843 \times 10^{-2} T + 2.5860 \times 10^{-5} T^2 - 2.8497 \times 10^{-8} T^3$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{ K}^{-1}$  and  $T$  is the temperature in kelvin. The heat capacity of methanol vapor is  $42.59 \text{ J mol}^{-1} \text{ K}^{-1}$  at  $273.15 \text{ K}$  and  $44.06 \pm 0.03 \text{ J mol}^{-1} \text{ K}^{-1}$  at  $298.15 \text{ K}$ .

The heat capacity of liquid methanol between  $176$  and  $368 \text{ K}$  is given by

$$C_p = 74.86 - 0.102315 T + 4.066567 \times 10^{-4} T^2$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{ K}^{-1}$  and  $T$  is the temperature in kelvin [18]. A similar polynomial gives the heat capacity of liquid methanol between  $175.5$  and  $493 \text{ K}$  ( $-97.6$  and  $+220 \text{ }^\circ\text{C}$ ) as

$$c_p = 0.8382 - 3.231 \times 10^{-3} T + 8.296 \times 10^{-6} T^2 - 0.1689 \times 10^{-9} T^3$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ }^\circ\text{C}^{-1}$  and  $T$  is the temperature in kelvin [6]. The heat capacity of liquid methanol at  $298 \text{ K}$  is  $2.544 \text{ J g}^{-1} \text{ K}^{-1}$  ( $0.608 \text{ cal g}^{-1} \text{ }^\circ\text{C}^{-1}$ ). Other sources give a heat capacity of liquid methanol at  $298 \text{ K}$  of  $80.22 \text{ J mol}^{-1} \text{ K}^{-1}$ , which appears to be in error.

#### 1.2.7.2 Enthalpy of Formation and Heat of Combustion of Methanol

The average enthalpy of formation of methanol vapor from nine different sources was  $-205 \pm 10 \text{ kJ/mol}$  (NIST). For liquid methanol, one source [19] reported a value of  $\Delta H_f^{298} = -238.9 \pm 3.6 \text{ kJ/mol}$ , based on a calorimetrically measured heat of combustion of  $726.5 \pm 0.2 \text{ kJ/mol}$ . The difference between these two numbers is the heat of evaporation.

Isotope labeling is helpful when assigning bonds in vibrational spectra. Structural and spectroscopic data on  $\text{CH}_3\text{OH}$ ,  $\text{CH}_3\text{OD}$ , and  $\text{CD}_3\text{OD}$  were reviewed and used

in using rigid rotor and harmonic oscillator models to calculate ideal gas thermodynamic properties in the temperature range from 0 to 1500 K [20]. Experimental data for the standard enthalpy of formation at 298.15 K, the heat capacities, and the third-law entropies at elevated temperatures are available only for the CH<sub>3</sub>OH vapor phase, where intermolecular association occurs. The agreement between the observed thermal data and the calculated values is satisfactory within the experimental uncertainties.

### 1.2.7.3 Heat of Fusion of Methanol

The heat of fusion of methanol at 175.3 K is 3.18 kJ/mol. Frozen methanol exists in two crystal modifications. Thermal properties of solid methanol were studied by adiabatic calorimetry [21].

### 1.2.7.4 Heat of Vaporization of Methanol

One method to derive the heat of vaporization at other temperatures if one data point is known is to use the Watson equation:

$$\Delta H_{\text{vap}} = \Delta H_{\text{vap}1} [(T_c - T)/(T_c - T_1)]^n$$

where  $\Delta H_{\text{vap}1}$  is the heat of vaporization at a known temperature  $T_1$  (assumed to be 260.1 cal/g at  $T_1 = 337.8 \text{ K} = 64.7^\circ\text{C}$ ),  $T_c$  is the critical temperature ( $512.5 \text{ K} = 239.4^\circ\text{C}$ ), and  $n$  ( $= 0.4$ ) is an empirical coefficient. The average of 11 literature data points gave a heat of vaporization of  $37.6 \pm 0.5 \text{ kJ/mol}$  [3].

## 1.3 Chemical Properties of Methanol

The procurement of methanol for government applications may depend on Fed. Spec. O-M-332 Rev. N (Feb. 2016).

### 1.3.1 Thermal Stability of Methanol

When used as a fuel in bipropellant rocket engines, methanol has the advantage that it can be used as regenerative coolant without needing to worry about soot deposition in the cooling channels. Methanol pyrolyzes to gaseous products and does not leave any carbon residues.

## 1.4 Compatibility with and Corrosion of Materials in Methanol

Methanol contamination that was negligently left behind in tanks after center-of-gravity, spin-balance, and vibration tests caused stress corrosion of titanium

alloy tanks during the Apollo program [22]. Stress-corrosion cracking of the alloy Ti-6Al-4V in methanol was investigated using small (laboratory-scale), bent-beam, self-stressed specimens and surface-precracked tensile specimens under constant load [23]. The alloy was tested after it had been either annealed, solution-treated, or solution-treated and aged. Tests were conducted at ambient temperature and pressure in reagent methanol (99.9 mol-% pure) and in methanol containing chloride ion concentrations of 5, 10, 100, and 500 ppm added as concentrated hydrochloric acid. Self-stressed specimens were tested with outer stress levels of 25, 50, and 100 ksi (170, 340, and 690 MN/m<sup>2</sup>), and precracked specimens were tested with initial stress intensity parameters ranging from 4 ksi (in.)<sup>1/2</sup> (4.4 MN m<sup>-2</sup> m<sup>1/2</sup>) to the critical stress intensity value of the material. In the self-stressed specimen tests in reagent methanol, cracks initiated and propagated to failure in the solution-treated and aged material in as little as 15 h with initial outer fiber stresses of 100 ksi (690 MN/m<sup>2</sup>). Generally, the solution-treated and aged material had the least resistance to cracking, whereas the solution-treated material had the most resistance to cracking. In tests of self-stressed specimens, chloride ion additions of 5–500 ppm appeared to decrease the cracking time by an order of magnitude as compared with the cracking time in reagent methanol, but there seemed to be little variation in cracking time for the range of chloride contents applied in this investigation. Halide contamination from halocarbons used as degreasing cleaning fluids can have the same effect.

Even if ethanol is used instead of isopropanol as a cleaning fluid for titanium alloy tanks, the traces of methanol commonly found in poor-grade agricultural ethanol may cause the same problem. The preferred cleaning solvent for titanium alloy tanks is isopropanol and not ethanol. If ethanol of dubious quality is used instead of isopropanol, stress corrosion of titanium alloy tanks can be avoided by adding at least 5% water to the ethanol.

## 1.5 Toxicity of Methanol

Methanol is more toxic than ethanol and has been the cause of numerous tragic poisoning incidents in which it was accidentally mistaken for ethanol or deliberately or negligently mixed into the ethanol by moonshiners and bootleggers.

## 1.6 Environmental Effects of Methanol

Methanol is a more environmentally friendly automotive fuel than gasoline because it results in cleaner engine exhaust and would be easier to clean up in the case of a spill. The same advantage would apply if it was ever used as a rocket fuel. But, of course, the vehicle fuel economy would be worsened by switching from gasoline to methanol.

1.7 Explosive and Fire Hazards of Methanol

The flammable range of methanol vapor in air is 6.7–36 vol.-% (at 333 K = 60 °C), with upward propagation. The flammable range widens with temperature, as shown in Table 6.

**Table 6:** Lower limit of the flammability of methanol at different temperatures.

| Temperature |     | Lower limit, vol.-% |
|-------------|-----|---------------------|
| K           | °C  |                     |
| 373         | 100 | 6.65                |
| 423         | 150 | 6.15                |
| 473         | 200 | 5.80                |
| 523         | 250 | 5.45                |

Data source: [24]

The autoignition temperature of methanol in air is 658 K (385 °C). The open-cup flash point of methanol in air is 284 K (11 °C). The most complete summary of the flammability of methanol under a wide range of conditions (different pressures, diluents, directions of flame propagation, tube diameters, oxygen enrichments, and contaminants) is available in a NASA Handbook [25].

1.8 Applications of Methanol as Rocket Fuel

1.8.1 Applications of Methanol as Fuel in Bipropellant Rocket Engines

Specific combinations of methanol and methanol blends with hypergolic or non-hypergolic oxidizers will be described in future volumes of the *Encyclopedia of Rocket Propellants*.

Here we offer only a brief historical summary of the use of methanol as a fuel in rocket engines that serves as a justification for writing about methanol here in the fuels volume of the *Encyclopedia of Rocket Propellants*.

Methanol (“M-Stoff”) was the main fuel constituent in a fuel mixture described by the code name “C-Stoff” and used in the WALTER 109-501, 109-509, and 109-509A-2 rocket engines along with 95 mass-% hydrogen peroxide (“T-Stoff”) as the oxidizer. C-Stoff was a mixture of 57 mass-% methanol, 30 mass% hydrazine hydrate, and 13 mass-% water. These rocket engines were used in the Me-163B rocket-powered airplane and Natter manned interceptors.

The British used a combination of LOX and 60% methanol/40% water in the test missile RTV-1 during 1948–1952. Research test vehicle-1 (RTV-1) was intended as a development tool for testing antiaircraft missile components. It was launched by

a cluster of solid boosters and sustained by a liquid-propellant engine with 3.96 kN (900 lb<sub>f</sub>) of thrust. Initially it was supposed to operate on LOX/kerosene, but the high ionization in the luminescent plume interfered with radio signal transmission and a cooler-burning propellant combination was chosen [26, p. 849].

In the UK, Armstrong-Siddeley Ltd. developed the Snarler JATO engine in 1948 using LOX and diluted methanol. The Snarler JATO unit used LOX with water-diluted methyl alcohol, had 900 kg<sub>f</sub> or 1980 lb<sub>f</sub> of thrust, and was flight tested in a Hawker P-1072 aircraft [27].

### 1.8.2 Rocket Fuel Mixtures Containing Methanol

Methanol has been tested as a freezing-point depressant for hydrazine [28]. Methanol has the ability to act as a very effective freezing-point depressant for hydrazine without detracting too much from its value as a fuel in bipropellant combinations. A hydrazine-methanol mixture containing 45 mass-% hydrazine freezes at 228 K (−45°C) (Figure 1). When 40% hydrazine is present, the freezing point is 215 K (−58°C). The freezing points of this system are lowered further when water is added.

**Figure 1:** Freezing point diagram for methanol/hydrazine mixtures. (Reproduced and modified from [28].)

### 1.8.3 Applications of Methanol as a Fuel in Monopropellant Rocket Engines

Methanol has been used as the fuel in a number of HAN-based monopropellants, for example in a balloon-dropped supersonic test missile in Japan (see the chapter “Hydroxylammonium Nitrate-Based Monopropellants” in *Encyclopedia of Monopropellants*). 30% methanol was used as a diluent for glycerin trinitrate in one of the first monopropellant experiments carried out by Crocco and Corelli in Italy in the 1930s, where several liters of the propellant mixture were carried by one of the experimenters on a passenger train from Turin to Rome for use in a monopropellant reactor [29]. For-

tunately, the train arrived without any incidents. There was concern that evaporation of the more volatile methanol might result in a more sensitive propellant, and the decomposition reactor did indeed suffer a delayed explosion during cooldown following an otherwise successful test.

Methanol has been used as a diluent for nitromethane in liquid gun propellants [30].

#### 1.8.4 Other Applications of Methanol as a Fuel

Although its energy content is not nearly as high as that of gasoline, methanol can be used as an alternative fuel in internal combustion engines, jet engines, or even fuel cells. Numerous studies evaluating the use of methanol as an automotive fuel have been published [31]. Methanol can be converted to dimethyl ether, which can be used as an alternative diesel fuel that not only results in cleaner exhaust but may also alleviate our dependence on petroleum-derived hydrocarbons as diesel fuels.

## 2 Ethanol

Ethyl alcohol (ethanol,  $\text{C}_2\text{H}_5\text{OH}$ ,  $\text{C}_2\text{H}_6\text{O}$ , CAS RN [64-17-5]) was the first liquid rocket fuel to be used in large quantities during the 1930s and 1940s in Germany. In the US, Goddard also performed some rocket engine tests with LOX/ethanol but then reverted to LOX/gasoline for the remainder of his tests in New Mexico.

Diluted ethanol was the fuel used in the first mass-produced liquid-propellant ballistic missile (A-4, a.k.a. V-2), and it continued to be used in the US after some of the impounded V-2 missiles were reassembled and tested there. One of the first US-made V-2 derivatives, the Redstone IRBM, used 75 mass-% ethanol as fuel, and the booster for the Navaho cruise missile used 92.5% ethanol as fuel.

During the development tests in Peenemünde in the Baltic Sea in Germany, they initially used water-diluted ethanol containing only 75 mass-% ethanol because they could not manage the high chamber temperature of this rocket propellant combination with undiluted, water-free ethanol. Only later did applications of LOX/ethanol combinations in other countries make use of more concentrated and water-free ethanol. As rocket design progressed and engineering knowledge grew, the cooling problems with LOX/kerosene engines were eventually mastered and ethanol as a rocket fuel was abandoned in favor of kerosene, which gives a higher specific impulse than ethanol but burns much hotter.

Ethanol continues to receive attention as a rocket fuel because it is considered “non-toxic” (compared to hypergolic storable fuels based on hydrazines). However, it is not hypergolic with any non-fluorine oxidizers, and it requires an external source of ignition. The Dream Chaser reusable spacecraft built by Sierra Nevada Corp. uses nitrous oxide/ethanol thrusters for attitude control and deorbit propulsion.

## 2.1 Production of Ethanol

Information on the production and properties of ethanol is readily available in commonly used encyclopedias [32, 33]. Ethanol is widely used as a solvent, a germicide, a beverage, an anti-freeze, a fuel, and a chemical intermediate for other organic chemicals. Fermentation processes are the most important source of ethanol. In addition, industrial ethanol is produced from petroleum-derived ethylene by a direct hydration process. The subsidized (federal and state) use of fermentation ethanol in gasoline has fueled a rapid growth in US agricultural ethanol production. The US 1990 Clean Air Act requiring the use of oxygenates in gasoline has further driven this growth. Corn is the principal feedstock for fermentation in the United States, and sugar cane is the most important raw material outside the United States. Ethanol generation from cellulose (corn stalks, wood, saw dust) represents a valuable use of materials that would otherwise go to waste.

## 2.2 Physical Properties of Ethanol

The physical properties of ethanol are summarized in Table 7. In view of the renewed interest in ethanol as a rocket propellant, in particular as a “green,” environmentally friendly propellant, the current chapter on ethanol fills a data gap.

**Table 7:** Physical properties of ethanol.

| Property                                 | SI units                                      | Other units                                                 | References |
|------------------------------------------|-----------------------------------------------|-------------------------------------------------------------|------------|
| Molecular mass                           | 46.0684 g/mol                                 | 21.707 mol/kg                                               | [3]        |
| Freezing point                           | $158.8 \pm 0.7$ K                             | $-114.35 \pm 0.7$ °C                                        | [3]        |
| Boiling point                            | $351.5 \pm 0.2$ K                             | $78.4 \pm 0.2$ °C                                           | [3]        |
| Density at 293 K = 20 °C                 | 0.7893 g/cm <sup>3</sup>                      | —                                                           | [4]        |
| Vapor pressure at 293 K = 20 °C          | 5.862 kPa                                     | 44 mm Hg                                                    | [34]       |
| Dynamic viscosity at 288.7 K = 60 °F     | $0.012 \times 10^5$ $\mu$ N s m <sup>-2</sup> | 1.2 cPs = 0.012 Ps                                          | [4]        |
| Kinematic viscosity                      | $1.525 \times 10^{-6}$ m <sup>2</sup> /s      | 1.525 cSt                                                   |            |

### 2.2.1 Freezing Point and Phase Diagrams of Ethanol Mixtures

Ethanol is widely used as an anti-freeze, so its freezing point diagram in water has practical importance.

### 2.2.2 Density of Ethanol

The saturated liquid density of ethanol for the range 159–516.2 K (–114.1 to +243.1 °C) can be calculated from the equation

$$\rho = A \times B^{-[1-(T/T_c)]^{\frac{2}{7}}}$$

where  $\rho$  is the density in g/cm<sup>3</sup>, A and B are correlational constants (A = 0.2928, B = 0.2760),  $T_c$  is the critical temperature (512.5 K), and T is the temperature in kelvin [6]; see Figure 2.

**Figure 2:** Liquid density of methanol and ethanol. (Image created by Schmidt 2020 based on data from [6])

Specific gravity data for denatured ethanol-water and methanol-water mixtures were obtained by a pycnometric method at temperatures between 266 and 322 K (20–120 °F) with solutions containing between 22.5 and 100% alcohol [37]. Alcohols are added as anti-freeze to water solutions that are injected into jet engine combustors during takeoff to reduce temperatures and increase thrust.

### 2.2.3 Compressibility of and Velocity of Sound in Ethanol

The isothermal compressibility of ethanol at 293 K is  $1.098 \text{ GPa}^{-1}$ . Data on the velocity of sound in, the adiabatic compressibility of, and the density of ethanol as functions of pressure, as well as the corresponding data for methanol, are listed in Table 8.

**Table 8:** Data on the velocity of sound in, the density of, and the adiabatic compressibility of methanol, as well as the corresponding data for ethanol, as functions of pressure at 298 K (25 °C).

| Pressure, GPa   | Velocity of sound, km/s | Density, g/cm <sup>3</sup> | Compressibility, GPa <sup>-1</sup> |
|-----------------|-------------------------|----------------------------|------------------------------------|
| <b>Methanol</b> |                         |                            |                                    |
| 0.0001          | 1.10                    | 0.787                      | 0.96                               |
| 0.014           | 1.18                    | 0.797                      | 1.12                               |

Data source: [38]. See also [39].

A fundamental equation of state for ethanol expressing the Helmholtz energy as a function of temperature and density has been developed [40]. Ancillary equations include equations for vapor pressure, saturated liquid density, saturated vapor density, and ideal gas heat capacity. Results from both the fundamental and ancillary equations have been compared to experimental data. It was found that the fundamental equation can compute densities to within  $\pm 0.2\%$ , heat capacities to within  $\pm 2\%$ , and the velocity of sound to within  $\pm 1\%$  of their experimentally

determined values. Values of the vapor pressure and saturated vapor density were calculated to within  $\pm 1\%$  of their experimentally determined values at temperatures of 300 K and above, while saturated liquid densities were calculated to within  $\pm 0.3\%$  of their experimentally determined values at temperatures of 200 K and above. The equation was found to be valid for pressures of up to 280 MPa and temperatures from 160 to 650 K.

The compressibility of ethanol is important for predicting water hammer effects in propellant feed systems, which are primed for the first time by dropping fuel into evacuated lines (surge flow) or by suddenly shutting off valves while the propellant is flowing, causing water hammer pressure spikes. During start-up of the propulsion system of a satellite or spacecraft, opening the tank isolation valve will cause the propellant to flow into an evacuated feedline, and the column of moving liquid to slam against a closed thruster valve. This filling process, called priming, can cause severe pressure spikes that could lead to structural failure. In the case of monopropellants such as hydrazine, the risk of adiabatic compression detonation must also be taken into account in the design of the feedline subsystem. Ethanol was used as a safe surrogate fluid to measure pressure spikes in a typical feed system, with water used as a reference fluid and ethanol used as a representative organic fuel [41]. The phenomenon of priming involves complex two-phase flow: the liquid entering the evacuated pipe undergoes flash evaporation, creating a vapor cushion in front of the liquid that mixes with the residual inert gas in the line. In addition, the dissolved pressurizing gas in the liquid will desorb, making the priming process difficult to model. Tests were performed with water and ethanol at different conditions: different tank pressures, vacuum levels, pressurizing gases (helium vs. nitrogen), geometries, etc.

#### 2.2.4 Vapor Pressure of Ethanol and Vapor-Phase Compositions of Ethanol Mixtures

The vapor pressure of ethanol can be calculated by the Antoine equation

$$\log P = A - B/(T + C)$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. NIST gives three different sets of parameters for the three constants  $A$ ,  $B$ , and  $C$ , each for a different temperature range (Table 9 and Figure 3).

**Table 9:** Coefficients for the Antoine equation for the vapor pressure of ethanol.

| Temperature range, K | A       | B        | C       | References |
|----------------------|---------|----------|---------|------------|
| 364.8–513.91         | 4.92531 | 1432.526 | −61.819 | [7]        |
| 292.77–366.63        | 5.24677 | 1598.673 | −46.424 | [8]        |
| 273–351.70           | 5.37229 | 1670.409 | −40.191 | [42]       |

Data source: [3]

Note: Coefficients were calculated by NIST from the author's data.

**Figure 3:** Vapor pressure data for methanol and ethanol. (Image created by Schmidt 2020 based on data from [3].)

Another vapor pressure equation for the range 228–516 K uses five coefficients and the equation

$$\log p_V = A + \frac{B}{T} + C \log T + DT + ET^2$$

where  $p_V$  is the vapor pressure in mmHg and  $T$  is the temperature in kelvin. The correlation constants are  $A = -10.967$ ,  $B = -2212.6$ ,  $C = 10.298$ ,  $D = -21.061 \times 10^{-3}$ , and  $E = 10.748 \times 10^{-6}$ . For a temperature of 298 K, this equation gives a vapor pressure of 58 mmHg [6].

Accurate property data are essential for the design and evaluation of ethanol/water separation processes. Physical, chemical, and thermodynamic properties of ethanol, water and their mixtures have been compiled, including non-ideal vapor phase fugacity coefficients, liquid specific volumes, vapor pressures, reference fugacities, vapor/liquid equilibria, activity coefficients, vapor and liquid enthalpies, the effect of salt on the ethanol/water equilibrium, and multi-component equilibrium modeling [43]. The vapor phase above ethanol/water mixtures is rich in ethanol, which is of course the basis for the distillation of distilled spirits from wine. A very detailed investigation of vapor phase compositions for the ethanol/water system was conducted, based on predictions derived from a computational method. Predictions from the computational mode (Uniquac) very closely matched the measured values reported in the literature [44] (Figure 4).

Ethanol and water form an azeotrope at 96 mass-%  $C_2H_5OH$  and 101 kPa. This azeotrope is formed through hydrogen bonding between the two molecules, which

**Figure 4:** Liquid- and vapor-phase compositions of ethanol/water mixtures at 760 mm Hg, based on data from [44]. (Reproduced and modified from [43].)

is why absolute ethanol cannot be obtained by simple distillation. Heterogeneous azeotropic distillation has been studied using several entrainers: benzene, cyclohexane, trichloroethylene, or isooctane [45, 46]. Higher concentrations have been achieved by adding salts (sodium acetate) to the boiling mixture or by distillation with benzene as an auxiliary fluid. The resulting ethanol may contain some benzene as a contaminant and is thus no longer fit for human consumption.

### 2.2.5 Viscosity of Ethanol

Viscosity data for ethanol are summarized in Table 10.

**Table 10:** Viscosity of liquid ethanol.

| Temperature |    | Dynamic viscosity     |       | References |
|-------------|----|-----------------------|-------|------------|
| K           | °C | mN s m <sup>-2</sup>  | cPs   |            |
| 273         | 0  | $0.0179 \times 10^2$  | 1.790 | [34]       |
| 293         | 20 | $0.01716 \times 10^2$ | 1.716 |            |
| 343         | 70 | $0.01549 \times 10^2$ | 1.549 |            |
| 273         | 0  | $0.0177 \times 10^2$  | 1.77  | [14]       |

The viscosity of liquids can be expressed by a Fulcher-type equation

$$\log \eta = A + B/(T - T_0)$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The constants  $A$ ,  $B$ , and  $T_0$  for ethanol are summarized and compared to those for other associated (hydrogen-bonded) liquids in Table 3. In the case of ethanol, the equation would be

$$\log \eta = -2.4401 + 774.414/(T + 15.249)$$

which is applicable for temperatures between 175 and 343 K (−98.11 to +70 °C). At 298 K, this equation yields a viscosity of 1.08 cPs for ethanol with an error of  $\pm 2.6\%$ .

The dynamic viscosity of liquid ethanol in the range 273–343 K can be calculated from the following equation:

$$\eta = 5.276 \times 10^{13} T^{-5.530}$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The viscosity from this equation at 293 K is 1.2 cPs [12].

The dynamic viscosity of liquid ethanol in the range 168–516 K (−105 to +243 °C) can be calculated from the following equation:

$$\log \eta = A + \frac{B}{T} + CT + DT^2$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The coefficients for this equation are  $A = -2.697$ ,  $B = 700.9$ ,  $C = 0.2682 \times 10^{-2}$ , and  $D = -4.917 \times 10^{-6}$ . For example, the viscosity from this equation at 298 K is 1.04 cPs [10].

### 2.2.6 Surface Tension of Ethanol

The surface tension of a liquid can be predicted by a corresponding state method described by Brock and Bird, based on the boiling point temperature, critical temperature, and critical pressure. Once the surface tension at one temperature  $T_1$  is known, the surface tensions at other temperatures can be calculated by the Othmer relation. The surface tension of ethanol can be calculated from the following equation:

$$\sigma = \sigma_1 [(T_c - T)/(T_c - T_1)]^{\frac{11}{9}}$$

where  $\sigma$  is the surface tension in dyn/cm,  $T_c$  is the critical temperature (516 K), and  $T$  is the temperature in kelvin. The surface tension of ethanol is 22.39 dyn/cm at 293 K and 21.78 dyn/cm at 298 K [13]. A similar, older equation that applies in the range 159–516.2 K (−114.1 to +243.1 °C) used an exponent  $n = 0.8760$  instead of 11/9 [6]. Surface tension data for ethanol/water mixtures are listed in Table 11.

**Table 11:** Surface tension data for ethyl alcohol/water mixtures at 298 K (25 °C).

| Ethanol<br>Mass-% | Surface tension        |        |
|-------------------|------------------------|--------|
|                   | N/cm                   | dyn/cm |
| 40.0              | $2.963 \times 10^{-4}$ | 29.63  |
| 50.22             | $2.789 \times 10^{-4}$ | 27.89  |
| 59.58             | $2.671 \times 10^{-4}$ | 26.71  |
| 68.95             | $2.571 \times 10^{-4}$ | 25.71  |
| 77.98             | $2.473 \times 10^{-4}$ | 24.73  |
| 87.92             | $2.364 \times 10^{-4}$ | 23.64  |
| 92.10             | $2.318 \times 10^{-4}$ | 23.18  |
| 97.00             | $2.249 \times 10^{-4}$ | 22.49  |
| 100.00            | $2.203 \times 10^{-4}$ | 22.03  |

Data source: [47]

### 2.2.7 Thermal Conductivity of Ethanol

The thermal conductivity of ethanol as a saturated liquid can be calculated from the equation

$$\lambda = A + BT + CT^2$$

where  $\lambda$  is the thermal conductivity in  $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The correlation constants for ethanol in the temperature range 159–463 K (–114 to +190 °C) are  $A = 628.0$ ,  $B = -91.88 \times 10^{-2}$ , and  $C = 5.28 \times 10^{-4}$  [6]. At 293 K (+20 °C), the thermal conductivity of ethanol is  $404 \mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$ . The same equation in SI units is

$$\lambda = 0.2628 - 3.844 \times 10^{-4} T + 2.21 \times 10^{-7} T^2$$

where  $\lambda$  is the thermal conductivity in  $\text{W m}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin.

The thermal conductivity of ethanol vapor can be calculated from the polynomial equation

$$\lambda_G = A + BT + CT^2 + DT^3$$

where  $\lambda_G$  is the thermal conductivity of ethanol vapor at low pressure (approximately atmospheric pressure) in  $\mu\text{cal s}^{-1} \text{cm}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin. The correlation constants for ethanol in the temperature range 273–1273 K (0 to 1000 °C) are identical to those of methanol ( $A = -18.62$ ,  $B = 9.95 \times 10^{-2}$ ,  $C = 2.90 \times 10^{-4}$ , and  $D = -12.38 \times 10^{-8}$ ) [10]. See also [48, 49].

### 2.2.8 Heat Transfer Coefficient of Ethanol

A comparison of the heat transfer coefficients of methanol and ethanol is given in a section above on methanol.

The dependence of the Nusselt number for heat transfer on laminar/turbulent flow conditions can generally be expressed in the form

$$\text{Nu} = C \text{Re}^m \text{Pr}^n$$

Rates of heat transfer to supercritical ethanol in microchannels by forced convection were measured using small-diameter circular tubes fed by a pressurized fuel supply [50]. The test sections consisted of resistively heated stainless steel hypodermic needle capillary tubes that were 4 mm in length and had an inside diameter of 95  $\mu\text{m}$ . The test conditions (temperature, pressure, film Reynolds number, bulk Nusselt number, and heat flux) were selected such that most of the physical parameters that were expected in the cooling passages of a silicon-fabricated microrocket engine were duplicated at pressures of 100 and 300 atm, corresponding to supercritical reduced pressures of 1.62 and 4.86, respectively. Heat flux values ranged from 3 to 125  $\text{W}/\text{mm}^2$ . The measured bulk Nusselt numbers ranged from 15 to nearly 400, with the corresponding film Reynolds numbers ranging from 500 to over 100000. Experimental results indicated that ethanol is a suitable fuel for regeneratively cooled microrocket engines. Post-test inspection of the inner tube wall of one of the test sections indicated that carbon deposition resulting from the pyrolysis of ethanol was not an issue.

Electrically heated tube tests were conducted to characterize the critical heat flux (for the transition from nucleate to a boiling film) of a subcritical 95 mass-% ethanol/5% isopropanol mixture flowing at conditions relevant to the design of a regeneratively cooled rocket engine thrust chamber at pressures of 1–4.8 MPa (144–703 psia), flow velocities of 9.7–77 m/s, coolant subcooling of 274–456 K (33–362 °F), and critical heat fluxes of up to 1422  $\text{W}/\text{cm}^2$  (8.7  $\text{BTU in}^{-2} \text{s}^{-1}$ ) [51]. For the data taken near to 1.38 MPa (200 psia), the critical heat flux was correlated with the product of velocity and fluid subcooling to within 20%. For data taken at higher pressures, an additional pressure term was needed to obtain a correlation with the critical heat flux. Also, at higher test pressures and/or flow rates, exceeding the critical heat flux did not result in wall burnout. This result may significantly increase the engine heat-flux design envelope for higher-pressure conditions.

In a thermosyphon heat pipe, the overall heat transfer coefficient of the thermosyphon was found to increase with increasing heat flux and coolant flow rate. At a heat flux of 7.35  $\text{kW}/\text{m}^2$ , the overall heat transfer coefficient of ethanol was 0.17  $\text{kW m}^{-2} \text{°C}^{-1}$ , as compared to 0.126  $\text{kW m}^{-2} \text{°C}^{-1}$  for methanol and 0.16  $\text{kW m}^{-2} \text{°C}^{-1}$  for water [16].

### 2.2.9 Critical Constants of Ethanol

The critical constants of ethanol are  $T_c = 516.3\text{ K}$ ,  $p_c = 6383\text{ kPa}$ , and  $\rho_c = 0.2755\text{ g/cm}^3$ .

### 2.2.10 Thermodynamic Properties of Ethanol

Thermodynamic properties of ethanol are summarized in Table 12.

**Table 12:** Thermodynamic properties of ethanol

|                                                                 | SI units                                                           | Other units                                                                                  | References           |

$$M = 46.0684\text{ g/mol} = 21.707\text{ mol/kg}$$

Data on the heat capacity, free energy function, heat content function, heat content, and entropy of ethyl alcohol from 16 to 158 K (solid) and from 158 to 350 K (liquid) from calculations and measurements were tabulated and compared [56]. For the ideal gas state, these functions, together with the standard heat and free energy of formation, were tabulated from 0 to 1000 K. The best agreement between the experimental and calculated values of heat capacity and entropy was obtained with symmetrical three-fold barriers to free rotation of the CH<sub>3</sub> and OH groups of 13807 and 3347 J/mol (3300 and 800 cal/mol), respectively. See also [57–60].

### 2.2.10.1 Heat Capacity of Ethanol

The molar heat capacity of ethanol vapor assuming ideal gas behavior can be calculated from the polynomial equation [61]

$$C_p = 6.296 + 2.315 \times 10^{-1}T - 1.1856 \times 10^{-4}T^2 + 2.2218 \times 10^{-8}T^3$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin. Likewise, the molar heat capacity of ethanol vapor can be calculated from the polynomial equation

$$C_p = 0.239 + 62.3 \times 10^{-3}T - 38.06 \times 10^{-6}T^2 + 9.47 \times 10^{-9}T^3$$

where  $C_p$  is the heat capacity in  $\text{cal mol}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin.

The molar heat capacity of liquid ethanol between 159 and 381 K is

$$C_p = 100.92 - 0.1118386T + 4.9854 \times 10^{-4}T^2$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1} \text{K}^{-1}$  and  $T$  is the temperature in kelvin [18]. A similar polynomial gives the heat capacity of liquid ethanol between 159 and 453 K ( $-114.1$  and  $+180 \text{°C}$ ) as

$$c_p = -0.3499 + 9.559 \times 10^{-3}T - 37.86 \times 10^{-6}T^2 + 54.59 \times 10^{-9}T^3$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin [6]. The heat capacity of liquid ethanol at 298 K is  $0.58 \text{ cal g}^{-1} \text{°C}^{-1}$ .

Isochoric heat capacities of pure ethanol were measured with a high-temperature, high-pressure, adiabatic, and near-constant-volume calorimeter as a function of temperature and density [62]. Measurements were performed along 22 liquid and vapor near-critical isochores between  $193.32$  and  $365.5 \text{ kg/m}^3$  and from  $493.10$  to  $541.34 \text{ K}$ . The coverage included the one- and two-phase regions, the coexistence curve, and the near-critical and supercritical regions. The critical temperature and the critical density ( $T_c = 514.44 \pm 0.2 \text{ K}$  and  $\rho_c = 283.7 \pm 2 \text{ kg/m}^3$ ) for pure ethanol were extracted from the saturated properties near the critical point.

### 2.2.10.2 Enthalpy of Formation and Heat of Combustion of Ethanol

The enthalpy of formation of ethanol vapor behaving as an ideal gas can be calculated from the equation

$$\Delta H_f = -51.8 - 16.6 \times 10^{-3}T + 7.59 \times 10^{-6}T^2$$

where  $\Delta H_f$  is the heat of formation in  $\text{kcal/mol}$  and  $T$  is the temperature in kelvin.

### 2.2.10.3 Heat of Mixing of Ethanol Solutions

The ethanol/water system is extremely non-ideal, with both exothermic and endothermic heats of mixing observed, depending on the temperature and the mixture ratio [63]. At  $298.15$  and  $323.15 \text{ K}$ , mixing is exothermic, with extreme values of  $-775$  and  $-448 \text{ J/mol}$  at  $x$  values of about  $0.17$  and  $0.13$ , respectively (Figure 5).

**Figure 5:** Heat of mixing for the ethanol/water system, based on data from [63]. (Reproduced and modified from [43].)

#### 2.2.10.4 Heat of Vaporization of Ethanol

The heat of vaporization of ethanol in the temperature range 298–469 K can be calculated from the following equation [55]:

$$\Delta H_{\text{vap}} = 50.43 \exp(0.4475T/T_c) \left[ 1 - \left( \frac{T}{T_c} \right) \right]^{0.4989}$$

where  $\Delta H_{\text{vap}}$  is the heat of vaporization in kJ/mol at saturation pressure,  $T$  is the temperature in kelvin, and  $T_c$  is the critical temperature 513.9 K (Figure 6).

Another method to derive the heat of vaporization at other temperatures if one data point is known is to use the Watson equation:

$$\Delta H_{\text{vap}} = \Delta H_{\text{vap}1} [(T_c - T)/(T_c - T_1)]^n$$

where  $\Delta H_{\text{vap}1}$  is the heat of vaporization at a known temperature  $T_1$ , assumed to be 202.6 cal/g at  $T_1 = 351.4 \text{ K} = 78.3^\circ\text{C}$  (normal boiling point),  $T_c$  is the critical temperature (516.2 K = 243.1°C), and  $n$  ( $= 0.4$ ) is an empirical coefficient.

**Figure 6:** Heat of vaporization of ethanol. (Image created by Schmidt 2020 based on equation from [55].)

### 2.2.10.5 Heat of Fusion of Ethanol

The heat of fusion of frozen ethanol is 4.64 kJ/mol (1.109 kcal/mol) at 158.8 K [54]. Additional literature data for the enthalpy and entropy of fusion are shown in [3].

### 2.2.11 Optical Properties of Ethanol

#### 2.2.11.1 Absorption Spectrum of Ethanol

The IR spectrum of ethanol vapor is shown in Figure 7.

**Figure 7:** IR spectrum of ethanol vapor. (Reproduced and modified with permission from [64])

#### 2.2.11.2 Index of Refraction of Ethanol

Data for the index of refraction of ethanol are listed in Table 13.

**Table 13:** Index of refraction of ethanol.

| Temperature |      | Index of refraction ( $n_D$ ) |
|-------------|------|-------------------------------|
| K           | °C   |                               |
| 283.4       | 10.4 | 1.3621                        |
| 289         | 16   | 1.36048                       |
| 295         | 22   | 1.35967                       |
| 297         | 24   | 1.35885                       |
| 299         | 26   | 1.338.13                      |
| 303         | 30   | 1.35839                       |
| 307         | 34   | 1.33174                       |
| 309         | 36   | 1.3539                        |
| 311         | 38   | 1.35306                       |

Data source: [47]

**2.2.12 Electrical Conductivity of Ethanol**

The electrical conductivity of ethanol is  $1.50 \times 10^{-7}$  mho/cm at 273 K,  $6.4 \times 10^{-8}$  mho/cm at 291 K, and  $1.35 \times 10^{-9}$  mho/cm at 298 K.

**2.2.13 Dielectric Constant and Dipole Moment of Ethanol**

Data for the dielectric constant of ethanol are listed in Table 14. The dipole moment of ethanol is 1.63 Debye at 298 K. Other sources give the dipole moment of ethanol in the gas phase as 1.69 Debye.

**Table 14:** Dielectric constant of ethanol

| Temperature |        | Dielectric constant |
|-------------|--------|---------------------|
| K           | °C     |                     |
| 130.6       | -142.5 | 79.0                |
| 137.3       | -135.8 | 74.2                |
| 148.4       | -124.7 | 67.3                |
| 153.1       | -120.0 | 55.5                |
| 193.1       | -80.0  | 45.1                |
| 243.1       | -30.0  | 38.1                |
| 253.1       | -20.0  | 32.4                |
| 273.1       | 0.0    | 27.9                |
| 283.1       | 10.0   | 26.4                |
| 298.1       | 25.0   | 24.1                |
| 313.1       | 40.0   | 22.7                |
| 333.1       | 60.0   | 20.2                |

Data source: [47]

## 2.3 Chemical Properties of Ethanol

Ethanol is not very reactive and autoxidizes only very slowly in air. Bacterial fermentation converts it to vinegar. Ethanol is not very corrosive, making it easier to select suitable construction materials.

### 2.3.1 Thermal Stability of Ethanol

Ethanol is more thermally stable than hydrocarbons, but will pyrolyze at higher temperatures and may form some soot.

The rate constant for the disappearance of ethanol at temperatures between 849 and 897 K (576–624 °C) can be expressed by the equation

$$k_1 = 10^{10} \exp \left[ -46200 \pm \frac{1700}{RT} \right] \text{ s}^{-1}$$

and the principal products are acetaldehyde, hydrogen, and a polymeric product [65].

The gas mixture leaving a reactor during the thermal decomposition of ethanol at residence times of about 5 ms and temperatures from 1050 to 1275 K was analyzed by molecular beam sampling mass spectroscopy, and was found to consist of ethene, water, hydrogen, methane, and carbon monoxide, along with acetaldehyde as an intermediate [66–68]. The thermal decomposition of ethanol limits its use as a regenerative coolant in rocket engines. Adding some water to the ethanol fuel will extend its useful temperature range. This reaction can be used in the production of pyrolytic carbon and carbon nanotubes [69].

## 2.4 Handling of Ethanol

Compared to all other rocket fuels, ethanol is very safe to handle. Indeed, in the 1990s, when the call first went out to come up with environmentally friendly propellants, ethanol was one of the prime candidates for a “green” rocket fuel. At the same time, increasing quantities of ethanol were added to gasoline to reduce the exhaust toxicity and environmental impact of automobiles. Some automobiles were even modified to operate solely on ethanol as a gasoline replacement instead of using it as a gasoline additive.

### 2.4.1 Ethanol Fire Hazard

When handling ethanol in large quantities, the main hazard is the flammability of the material. The flammability safety properties of ethanol are listed in Table 15. The upper and lower flammability limits of ethanol vapor in air at 333 K (60 °C) with upward propagation are 3.28 and 19.00 vol.-%, respectively.

**Table 15:** Flammability safety properties of ethanol.

|                                                        |             |       |
|--------------------------------------------------------|-------------|-------|
| Flash point, open cup                                  | 294.3 K     | 70 °F |
| Flash point, closed cup                                | 285.9 K     | 55 °F |
| Lower limit of flammability in air, upward propagation | 3.3 vol.-%  |       |
| Upper limit of flammability in air, upward propagation | 19.0 vol.-% |       |

Data source: [36]

The flammable range widens with temperature, as shown in Table 16.

**Table 16:** Lower limit of flammability of ethanol at different temperatures.

| Temperature |     | Lower limit, vol.-% |
|-------------|-----|---------------------|
| K           | °C  |                     |
| 373         | 100 | 3.55                |
| 423         | 150 | 3.15                |
| 473         | 200 | 3.00                |
| 523         | 250 | 2.75                |

Data source: [24]

The autoignition temperatures and flammable ranges of ethanol and other combustibles must be known when investigating fire and explosion accidents [70]. The autoignition temperature of ethanol in air is 638 K (365 °C). The open-cup flash point of ethanol in air is 286 K (13 °C). The most complete summary of the flammability of ethanol under a wide range of conditions (in terms of pressure, diluents, direction of flame propagation, tube diameter, oxygen enrichment, and contaminants) is available in a NASA handbook [71].

The flammable range of ethanol vapor in air can be narrowed by adding a diluent gas. As seen in Figure 8, carbon dioxide is a more effective diluent gas than nitrogen. This is useful if there is an ethanol spill in a confined space and it is necessary to inert the atmosphere to prevent an explosion hazard. In this graph, the percentage of air in the ternary mixture was calculated from

$$\% \text{Air} = 100 - \% \text{Ethanol} - \% \text{Diluent}$$

#### 2.4.2 Spill Cleanup

If ethanol is spilled, it is easy to flush the spill away with copious amounts of water, diluting the flammable liquid to below the flash point. The open cup flash point of 100% ethanol is 288 K (15 °C), but after 1:1 dilution with water, the flash point of 50 vol.-% ethanol is above room temperature.

**Figure 8:** Flammable ranges of ethanol vapor/air/diluent gas mixtures. Note that the data obtained at higher concentrations along the dashed lines were obtained at a reduced pressure of 0.5 atm. (Reproduced and modified from [72].)

## 2.5 Toxicity of Ethanol

Besides the well-known hazard of drunkenness when ingesting ethanol in distilled spirits or other alcoholic beverages, there is the hazard of the inhalation of an excessive amount of ethanol vapor if any of the propellant is spilled during transfer and fueling operations. Working areas should be well ventilated, and the inhalation of ethanol vapors must be avoided as it can cause the same effects as imbibing the ethanol. An episode was reported where an engineer who was inspecting the inside of a warm LOX/EtOH rocket chamber to look for discoloration or burnt spots soon after a test firing, while the injector passages were still wet with liquid fuel, became intoxicated by inhaling the fumes [26].

The toxicity of ethanol is greatly increased by the addition of denaturing agents (methanol, pyridine, and benzene) to discourage consumption by humans.

### 2.5.1 Ethanol Inhalation Hazard

The NIOSH REL and OSHA PEL threshold limit value for ethanol for 8 h/d, 5 d/week exposure is 1000 ppm TWA. For vapor inhalation, the immediately dangerous to life and health (IDLH) concentration is 3300 ppm for 0.5 h (10% of the LEL flammability limit). At this concentration, the ethanol vapor in the air will irritate the eyes [73].

The original IDLH (15000 ppm) was based on human inhalation, but at 15000 ppm there is continuous lachrymation and coughing in exposed individuals. Other sources

have reported that a 2 h of exposure to 19260 ppm produced only light narcosis in the rat; that 255 min of exposure to 19260 ppm produced no signs of intoxication in the guinea pig; that 75 min of exposure to 23940 ppm produced narcosis in the mouse; and that 80 min of exposure to 13300 ppm caused ataxia in the mouse. The IDLH was revised to 3300 ppm based on health considerations and acute inhalation toxicity data in humans [74, 75].

### 2.5.2 Ethanol Splash Hazard

Ethanol spilled on the skin is relative harmless. Skin exposure to ethanol may dissolve some of the skin grease if the spills are repeated, so the skin may become dry and brittle. Alcohol splashed into the eyes will cause immediate eye irritation. Alcohol splashes into eyes should be rinsed out with water. Single splash incidents will rarely leave lasting effects.

## 2.6 Rocket Fuel Mixtures Containing Ethanol

Ethanol has been tested as a freezing point depressant for hydrazine [28]. Fuel blends containing 10 mass-% hydrazine or less freeze below 233 K ( $-40^{\circ}\text{C}$ ) (Figure 9). The lowest freezing mixture containing a greater amount of hydrazine is that with a composition of about 35 mass-% hydrazine and 65% ethanol, which freezes at 237 K ( $-36^{\circ}\text{C}$ ). The freezing point of this system is lowered further when water is added as a third constituent.

**Figure 9:** Freezing point diagram for ethanol/hydrazine mixtures. (Reproduced and modified from [28].)

## 2.7 Gelled Ethanol

Two gel fuels – ethanol gel and UDMH gel using methyl cellulose as a gelling agent – were rheologically characterized using a rheometer in the low shear rate range [76, 77]. The ethanol and UDMH gels were thixotropic in nature. Their apparent viscosity values fell drastically with the shear rate, and the apparent viscosities of the gels were significantly reduced at higher temperatures. For both gels, the up and down shear rate curves formed a hysteresis loop that showed no significant variation with temperature.

A rheological study of freshly prepared gelled ethanol was carried out using a rotational rheometer (HAAKE RS600) and the gel viscosity in the shear rate range  $1\text{--}1000\text{ s}^{-1}$  was assessed. A study of the gelation of metallized and non-metallized ethanol with a methylcellulose (MC) gelling agent and the rheological properties (flow and dynamic study) of these gels showed that increasing the shear rate reduced the apparent viscosity for a given yield stress (for a shear rate range of  $1\text{--}12\text{ s}^{-1}$ ) for both shear rate ranges ( $1\text{--}12$  and  $1\text{--}1000\text{ s}^{-1}$ ) covered in this experiment [78, 79]. The gellant (MC) and metal particle concentrations significantly influenced the apparent viscosity of the gel. Distinct changes in thixotropic behavior were observed while decreasing the concentrations of the MC and the Al metal particles in the ethanol gels. The dynamic study showed that all of the linear viscoelastic (LVE) regions of the gel samples were independent of the strain percentage ( $1\text{--}10\%$ ). The  $G'$  values depended on the frequency and exceeded the  $G''$  values, which indicated the presence of a highly structured, gel-like material. The values showed that all of the ethanol gels were elastic weak physical gels with a high degree of crosslinking.

The gelation of ethanol required a gellant concentration as low as 8 mass-% for the pure ethanol case and as low as 4 and 6 mass-% for metallized ethanol, depending on the metal type used [80]. Metallized gels using 20 mass-% Al and B metal powders showed a reduction in the required gellant concentration depending on the degree of metallization. The rheological properties of metallized and non-metallized ethanol gels with MC as the gelling agent at different ambient temperatures ( $283\text{--}323\text{ K}$ ) were experimentally investigated. The gel fuels were rheologically characterized using a rheometer at shear rates ranging from  $1$  to  $12\text{ s}^{-1}$  and from  $1$  to  $1000\text{ s}^{-1}$ . In the shear rate range  $1\text{--}12\text{ s}^{-1}$ , the apparent viscosities and yield stresses of the gels were observed to significantly decrease at higher ambient temperatures and as the gellant and metal particle concentrations decreased. The thixotropic behavior was found to be a strong function of the Al and B metal particle concentration for all test temperatures in the shear rate ranges from  $1$  to  $12\text{ s}^{-1}$  and from  $1$  to  $1000\text{ s}^{-1}$ . It was also a function of the MC concentration in the shear rate range of  $1\text{--}1000\text{ s}^{-1}$ . The hypergolicity and ignition delay of pure and energized ethanol gel fuel activated with metal catalysts and squirted together with hydrogen peroxide were tested in an open spot plate apparatus [81].

If a large gelling agent (methylcellulose or hydroxypropyl methyl cellulose) concentration is used, the gelled ethanol may be stiff enough to be used as a fuel grain in a hybrid rocket [82].

### 2.7.1 Gelled Metallized Ethanol

The specific impulse of ethanol as a fuel can be improved by the addition of metal powders with high heats of combustion, such as aluminum or beryllium. In order to keep the metal particles in suspension, the fuel has to be gelled.

The gelation of liquid fuels can be achieved at gellant concentrations as low as 8 mass-% for pure ethanol and as low as 4–6 mass-% for metallized ethanol (depending on the metal type). The rheological properties of metallized and non-metallized ethanol gels with methyl cellulose as a gelling agent at different ambient temperatures (283–323 K) were characterized at shear rates ranging from 1 to 12 s<sup>-1</sup> and from 1 to 1000 s<sup>-1</sup> using a rheometer [83]. In the shear rate range 1–12 s<sup>-1</sup>, the apparent viscosities and yield stresses of the gels were observed to significantly decrease at higher ambient temperatures and as the gellant and metal particle concentrations decreased. The thixotropic behavior was found to be a strong function of the A1 and B metal particle and gellant concentrations for all test temperatures at shear rate ranges of 1–12 and 1–1000 s<sup>-1</sup>.

Impinging jets of metallized and non-metallized ethanol gels with methyl cellulose as a gelling agent have been evaluated for their atomization characteristics using an injector design that induced disturbances prior to jet impingement due to the presence of a resonant cavity [84]. The effect of metallization on the spray characteristics of the fluid was recorded using a high-speed imaging system. A reduction in the mean droplet diameter of the metallized gel was observed when compared to the pure fuel gel, which may be due to the reduced cohesive forces in the metal-containing gel structure.

## 2.8 Substituted Ethanols

Ethanol is a good rocket fuel but not quite as energetic as one might wish. Therefore, attempts have been made to boost the energy content of ethanol by attaching explosophoric groups such as azido or nitro groups to the hydrocarbon skeleton that also carries the hydroxyl group.

Ethanol derivatives that carry explosophoric groups on the C<sub>2</sub> skeleton will be discussed in the sections focusing on explosophoric groups, not in this section. One example is 2-azidoethanol, which has been tested as a monopropellant and as a fuel. 2-Azidoethanol is described in the chapter “Azides and Azido Compounds” in *Encyclopedia of Liquid Fuels*. Ethanolamine is described in the chapter “Aliphatic Amines” in *Encyclopedia of Liquid Fuels*.

### 3 Isopropyl Alcohol

Isopropyl alcohol (2-propyl alcohol, 2-propanol, isopropanol, IPA, dimethylcarbinol, secondary propyl alcohol,  $(\text{CH}_3)_2\text{CHOH}$ ,  $\text{C}_3\text{H}_7\text{OH}$ , CAS RN [67-63-0]) is used mostly as a cleaning fluid and only rarely as a rocket fuel. The name isopropanol is incorrect because there is no alkane hydrocarbon by the name of *isopropane* from which this name could be derived by adding the suffix *-ol*. Nevertheless, some of its properties are included here because residual impure IPA accidentally left in the equipment after cleaning may adversely interact with rocket propellants and cause contamination problems. The properties of IPA, such as its vapor pressure and its tendency to autoxidize and form acetone and peroxides, need to be known to ensure the complete removal of IPA by evacuation or by purging with nitrogen before the propulsion system is loaded with propellants.

Isopropyl alcohol has been evaluated as a rocket propellant with NTO, LOX, HTP, or RFNA as the oxidizer, but there has been no additional work in this field recently [85–88]. Isopropyl alcohol can be hypergolized by adding aniline as the fuel [86].

#### 3.1 Production of Isopropyl Alcohol

Isopropyl alcohol can be prepared from ethylene via oxo synthesis, from propane by partial oxidation, or from propylene. Isopropyl alcohol is produced in industrial quantities and has many applications as a solvent and as an intermediate for other organic chemicals. Isopropyl alcohol has been used in the production of hydrogen peroxide.

#### 3.2 Physical Properties of Isopropyl Alcohol

Physical properties of isopropyl alcohol are summarized in Table 17. The vapor pressure of 2-propanol can be calculated from an Antoine equation using the coefficients listed in Table 18,

$$\log P = A - B/(T + C)$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. NIST gives two different sets of parameters for the three constants  $A$ ,  $B$ , and  $C$ , each for a different temperature range (Table 18).

Isopropyl alcohol and water form an azeotrope that contains 12.6 mass-%  $\text{H}_2\text{O}$  and boils at 353.5 K (80.4 °C). The dynamic viscosity of liquid 2-propanol in the range 273–353 K can be calculated from the following equation:

$$\ln \mu = -8.0339 + 2606.8/T$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The viscosity at 293 K is 2.3702 cPs [12].

**Table 17:** Physical properties of isopropyl alcohol.

| Property                                         | SI units                                    | Other units                                                 | References |

|----------------------|---------|----------|---------|
| 395–508              | 4.57795 | 1221.423 | −87.474 |
| 330–362              | 4.8610  | 1357.427 | −75.814 |

Note: Coefficients were calculated by NIST from the author's data.

The velocity of sound in isopropyl alcohol was measured by a single-pulse technique for temperatures from 294 to 366 K (70–200 °F) and for pressures from 0.1 to 4 MPa (1–40 atm) [5]. The IR spectrum of IPA is shown in Figure 10. Isopropyl alcohol/hydrazine mixtures containing 20 mass-% or more hydrazine freeze above 233 K (−40 °C). Isopropyl alcohol is not a very effective freezing-point lowering additive to hydrazine.

### 3.3 Chemical Properties of Isopropyl Alcohol

Most of the isopropyl alcohol procured by the US Government is used as a cleaning solvent and not as a rocket propellant. Nevertheless, the military specification for iso-

**Figure 10:** Infrared spectrum of 2-propanol vapor. (Reproduced and modified with permission from [64])

propyl alcohol (*MIL-P-87931 – Propellant, Isopropyl Alcohol*) calls it a propellant. Other specifications have been issued by ASTM [90, 91] and the Federal Government [92].

Although isopropyl alcohol is not used as a propellant, its purity when used as a cleaning solvent in propulsion systems must be controlled, otherwise residues left behind after the cleaning solvent evaporates could gum up valve seat surfaces or clog filter screens.

There was an incident where an excessively high acetone content of aged IPA was left behind in an incompletely dried tank system. When the system was later loaded with hydrazine, a reaction between the acetone and hydrazine (hydrate) formed a brown polymer goo that clogged filters in a ground service cart for fueling a satellite at the launch site. The only solvent capable of dissolving the brown residue and cleaning the cart was hydrazine.

Acetone and isopropyl peroxide form during the storage of IPA if air is not excluded and if the IPA is exposed to sunlight in a clear glass bottle. Most space system facilities do not specify that IPA cleaning solvents should be stored under an inert atmosphere. Most IPA procurement specifications do not limit the amount of acetone allowed in IPA when it is shipped from the supplier. The specifications only limit the levels of acidity (assumed to be acetic acid), non-volatile residues, and water.

Attempts to purify IPA (i.e., to recycle used IPA) by distillation have ended in catastrophe because less volatile peroxides accumulated in the sump of the still and exploded toward the end of the distillation process [93–95]. If IPA is to be recycled and purified by distillation, the peroxides must first be destroyed by reaction with a reducing agent.

There is (was) a commercial industrial process for the production of hydrogen peroxide based on the reaction of IPA with oxygen (see the chapter “Hydrogen Peroxide” in *Encyclopedia of Oxidizers*).

### 3.4 Toxicity of Isopropyl Alcohol

The NIOSH TWA and the OSHA PEL TWA for IPA are 400 ppm (980 mg/m<sup>3</sup>). The IDLH is 2000 ppm (4920 mg/m<sup>3</sup>).

### 3.5 Safety Properties of Isopropyl Alcohol

Isopropyl alcohol is a flammable liquid. Flammability data for isopropyl alcohol are shown in Table 19.

**Table 19:** Flammability properties of isopropyl alcohol.

| Property                        | Temperature                        |        | References |
|---------------------------------|------------------------------------|--------|------------|
| Flash point (open cup)          | 294 K                              | 21 °C  | [89]       |
| Autoignition temperature in air | 746 K                              | 473 °C | [89]       |
|                                 | 713 K                              | 440 °C | [96]       |
| Limits of flammability          | Lower limit: 2.2 vol.-%            |        | [72]       |
| Limits of flammability          | 2.02–7.99 vol.-% at 333 K = 60 °C  |        | [97]       |
|                                 | 1.73–7.35 vol.-% at 403 K = 130 °C |        |            |

## 4 Higher Alkanols (C<sub>n</sub> > 3)

Alkanols with more than three carbon atoms in the molecule have not been used as rocket propellants.

### 4.1 Furfuryl Alcohol as Rocket Fuel

Furfuryl alcohol (2-furymethanol, 2-furanmethanol, 2-furancarbinol, furfuranol, C<sub>5</sub>H<sub>6</sub>O<sub>2</sub>, CAS RN [98-00-0]) is an unsaturated cycloaliphatic alcohol that was, at one time, widely used as a hypergolic fuel in mixtures with aromatic or aliphatic amines in combination with nitric acid (WFNA or RFNA) as the oxidizer. It is listed here only for historical reasons. Most publications on the use of furfuryl alcohol as a rocket propellant are at least 60 years old. It is very unlikely that furfuryl alcohol will ever again be used as a rocket propellant, but if they do, they can claim to be using a sustainable biofuel, made from agricultural waste products without the use of fossil fuels, a true “green,” i.e., environmentally friendly rocket fuel. Furfuryl

alcohol is a five-membered furan ring with a hydroxymethyl group attached at the 2-position. The structural formula of furfuryl alcohol is shown here:

## 4.2 Production of Furfuryl Alcohol

Furfuryl alcohol is manufactured industrially by the catalytic reduction of furfural (its corresponding aldehyde), which is obtained from corncobs and sugar cane bagasse. Because it is made from regenerable raw products, it has been called a “biofuel.” It can be used as a solvent, but is primarily used as an ingredient in the manufacture of polymers for foundry resins, adhesives, and wetting agents. There are only a few other applications for furfuryl alcohol, so very little is produced. The use of furfuryl alcohol as a rocket propellant is now only of historical interest.

## 4.3 Physical Properties of Furfuryl Alcohol

Physical properties of furfuryl alcohol are listed in Table 20.

**Table 20:** Physical properties of furfuryl alcohol.

|                                                                    | SI units                                   | Other units                                  | References |
|--------------------------------------------------------------------|--------------------------------------------|----------------------------------------------|------------|
| Molecular mass                                                     | 98.0999 g/mol                              | 10.1934 mol/kg                               | [3]        |

The velocity of sound in furfuryl alcohol and aniline/furfuryl alcohol mixtures was measured by a single-pulse technique for temperatures from 294 to 366 K (70–200 °F) and for pressures from 0.1 to 4 MPa (1–40 atm) [5].

Viscosity data for furfuryl alcohol obtained with a rolling ball viscometer constructed from glass are listed in Table 21.

**Table 21:** Dynamic viscosity of furfuryl alcohol.

| Temperature |     | Viscosity              |       |

The IR spectrum of furfuryl alcohol is shown in Figure 11.

**Figure 11:** IR spectrum of furfuryl alcohol. (Reproduced and modified with permission from the NIST Standard Reference Data Program Collection in [3])

#### 4.4 Chemical Properties of Furfuryl Alcohol

Furfuryl alcohol in the freshly distilled state is a clear, yellowish liquid that discolors with age, turning dark red and finally dark brown due to autoxidation and polymerization.

Furfuryl alcohol is miscible with water, but solutions may autoxidize. It is soluble in most common organic solvents. When it comes into contact with acids, it will poly-

merize and form brown resins that are likely to clog valves, filters, and injector orifices. Addition of hydrazine, aniline, or alkylamines will suppress the resin formation.

The purity requirements for furfuryl alcohol, which was at one time procured by the US Government for use as rocket propellant, were spelled out in the military specification MIL-P-45702A – *Propellant, Furfuryl Alcohol* (now canceled) [99]. The requirements were max. furfural content 0.7%, max. cloud point  $295\text{ K} = 22^\circ\text{C}$ , refractive index ( $n_D$ )<sup>20</sup>  $1.486 \pm 0.003$  at  $293\text{ K} = 20^\circ\text{C}$ , and specific gravity  $1.135 \pm 0.006$  at  $293\text{ K} = 20^\circ\text{C}$ . The most likely contaminant was the aldehyde furfural, from which it was made by hydration. Furfural, a contaminant of furfuryl alcohol resulting from incomplete reduction or partial autoxidation, can be analyzed by infrared spectroscopy [100].

#### 4.4.1 Storage Stability of Furfuryl Alcohol

A significant disadvantage of furfuryl alcohol as a rocket fuel is its tendency to autoxidize and polymerize and form resins during storage. These resins may coat filters or orifices and obstruct flow. Resins plating out on the cooling channels of a regeneratively cooled rocket engine may cause burnout because heat transfer is locally impeded [101]. The resins are formed as a result of polymerization and polycondensation. Resin formation is accelerated by heat, oxygen from the air, light, and traces of acids. Basic or alkaline substances in furfuryl alcohol inhibit the reactions leading to resinification. Hydrazine or tertiary amines are the most effective inhibitors tested.

#### 4.5 Fuel Mixtures with Furfuryl Alcohol

Addition of aniline reduces the rate of resin formation by furfuryl alcohol somewhat. Furfuryl alcohol/aniline mixtures have been used in JPL-developed rockets in combination with WFNA or RFNA as the oxidizer, and there are numerous reports dating back to the 1940s on ignition delay measurements and static rocket engine tests with this propellant combination. The additive that most effectively prevents resin formation is hydrazine, since it acts as an antioxidant. Hydrazine also improves the hypergolic ignition quality of such fuel mixtures.

A 50:50 mixture of furfuryl alcohol and aniline was used in one version of the first American liquid-propellant ballistic missile, the MGM-5 CORPORAL developed by JPL, Douglas Aircraft, and Firestone Rubber for the US Army and deployed during the years 1954–1964. This missile was capable of carrying a payload of 680 kg, including nuclear warheads. An early version of the CORPORAL E used a fuel consisting of 80 mass-% aniline and 20 mass-% furfuryl alcohol. The oxidizer was RFNA with 6.5 mass-%  $\text{NO}_2$ . The later Type II CORPORAL used a mixture of 46.5 mass-% furfuryl alcohol, 46.5 mass-% aniline, and 7 mass-% hydrazine as the fuel and stabi-

lized IRFNA with 14 mass-%  $\text{NO}_2$ , 2.5%  $\text{H}_2\text{O}$ , and 0.6% HF [102, 103]. The liquid-propellant missile CORPORAL was later replaced by the solid-propellant missile SERGEANT. The 50:50 mixture of furfuryl alcohol and aniline ignites hypergolically with WFNA or RFNA, burns very smoothly without combustion instability, and can be used to cool the engine regeneratively. A bibliography of JPL publications contains more than 50 references to the CORPORAL missile, although not all of those relate to its propulsion and propellants [104]. The heat capacity of furfuryl alcohol/aniline mixtures in the range 300–422 K (80–300 °F), which was needed to calculate the regenerative cooling capability of this fuel in a rocket engine, was determined by calorimetric measurements [105].

A fuel mixture of 46.5 mass-% furfuryl alcohol and 51 mass-% aniline covered by MIL-P-45700 was also used in a US Navy surface-to-air missile called LARK. This fuel mix was similar to the fuel used by the US Army in the early version of the CORPORAL missile.

Although it is very unlikely that furfuryl alcohol/aniline mixtures will ever be used again as rocket fuels, we now review some physical properties of these mixtures. The specific heats of **(1)** a sample of aniline purified by fractional distillation, **(2)** a sample of commercial furfuryl alcohol, and **(3)** a sample of a mixture of 80 mass-% commercial aniline with 19.976 mass-% commercial furfuryl alcohol were determined by an adiabatic technique in a glass calorimeter at temperatures near to 311, 344, 378, 411, and 444 K (100, 160, 220, 280, and 340 °F, respectively) [106]. The specific heat of nitromethane was determined at temperatures near 311, 344, and 372 K (100, 160, and 210 °F, respectively) for comparison.

The specific heats of furfuryl alcohol-aniline mixtures containing mass fractions of 0.000, 0.2184, 0.4247, 0.6248, 0.8213, and 1.000 furfuryl alcohol in aniline were determined in a stainless-steel calorimeter [107]. The temperature ranges for these mixtures were approximately 322–447, 305–386, 300–378, 305–369, 305–369, and 305–339 K (120–345, 90–235, 80–220, 90–205, 90–205, and 90–150 °F), respectively. Both the aniline and the furfuryl alcohol used in these experiments were fractionally distilled for purification. About 0.1% piperidine was added to the furfuryl alcohol to retard decomposition.

The isobaric specific heats and viscosities of a mixture of aniline, furfuryl alcohol, and tetraethyl orthosilicate were determined at bubble-point pressure and various temperatures in the range from 305 to 378 K (90–220 °F) [108].

Densities and heat capacities of furfuryl alcohol/aniline mixtures were measured over the entire range of compositions and in the temperature range 283–363 K (10–90 °C) for density measurements and 313–393 K (40–120 °C) for heat capacity measurements, as listed in Tables 22 and 23 [109].

**Table 22:** Smoothed density values for furfuryl alcohol-aniline mixtures at the bubble point.

<sup>a</sup> Extrapolated values

Data source: [109]

The addition of 26 mass-% of hydrazine to furfuryl alcohol lowers the freezing point of the latter to 232.6 K (−40.5°C) [28]. The ignition properties of this mixture are slightly superior to those of furfuryl alcohol alone. Additions of as much as 5% water to this hydrazine-furfuryl alcohol solution depress the freezing point even further.

Another fuel mixture developed by JPL for a similar application had even better fuel properties. It consisted of 46 mass-% furfuryl alcohol, 47 mass-% aniline, and 7 mass-% hydrazine.

Furfuryl alcohol fuel blends were also used in other countries. Rocket engines developed at SEPR (later SEP) in France and used in the development of the two-stage solid-liquid anti-aircraft missile SE-4300 and the SEPR-48 engines used in TRI-DENT and MIRAGE rocket planes used a fuel mixture called Furaline, consisting of 41 mass-% furfuryl alcohol, 41 mass-% xylydine, and 18 mass-% methyl alcohol [110–112].

At one time, mixtures of furfuryl alcohol and triethylamine were used as hypergolic fuels. Such mixtures could be analyzed by gas chromatography [113].

Hypergolic fuels have been created by blending furfuryl alcohol (used as a solvent) with an ionic liquid, 1-ethyl-3-methyl imidazolium cyanoborohydride, in different volume proportions (80:20, 70:30, 60:40, 50:50, and 40:60) [114]. The blends exhibited good stability (chemical and thermal), low viscosity ( $\eta < 15$  mPa·s), high density ( $\rho > 1$  g/cm<sup>3</sup>), low ignition delay, and high performance in comparison to UDMH.

#### 4.5.1 Thermal Decomposition of Furfuryl Alcohol/Aniline Blends

The use of a mixture of 80% aniline and 20% furfuryl alcohol as fuel in regeneratively cooled rocket motors was hampered by the formation of gum-like deposits that gradually clogged the cooling passages. This gum formation was caused by rapid polymerization of the furfuryl alcohol while it was flowing through the cooling jacket. A program was initiated to find the threshold temperature for polymer formation so that a cooling system could be designed to operate below this temperature and thus eliminate the problem [115].

#### 4.5.2 Analytical Methods for Furfuryl Alcohol/Aniline Blends

Another fuel mixture developed by JPL for a similar application had even better fuel properties. It consisted of 46 mass-% furfuryl alcohol, 47 mass-% aniline, and 7 mass-% hydrazine. JPL also developed analytical methods for the analysis of such fuel mixtures [116, 117]. A simplified chemical method for testing the acceptability of rocket-fuel mixtures containing furfuryl alcohol, aniline, hydrazine, and water consisted of determining the amount of hydrazine and water present in the fuel, since these are the most critical constituents with regard to rocket-propulsion systems. Hydrazine was analyzed by the standard method employing chloramine-T. Water

was determined by measuring the hydrogen pressure that developed when the fuel reacted with calcium hydride.

The hydrazine contents of furfuryl alcohol/aniline/hydrazine mixtures can be determined by titrimetric methods [118]. One of the first storable hypergolic liquid fuels used in the United States was a mixture of aniline, hydrazine, and furfuryl alcohol. This mixture needed to be analyzed frequently to verify its storability [119]. The composition and purity requirements for this fuel were described in military specification *MIL-P-45700 – Propellant Mixture, Guided Missile, Aniline-Furfuryl Alcohol* (publication date: 10 March 1961), which is no longer available [99]. The requirements are listed in Table 24.

**Table 24:** Military specification *MIL-P-45700 – Propellant Mixture, Aniline-Furfuryl Alcohol*.

| Constituent      | Composition, mass-%                                         |
|------------------|-------------------------------------------------------------|
| Furfuryl alcohol | 46.3–46.7                                                   |
| Hydrazine        | 6.8–7.2                                                     |
| Water            | 1.5 max.                                                    |
| Other            | 0.7 max.                                                    |
| Aniline          | Balance, remainder to 100%                                  |
| Specific gravity | 1.070–1.085 g/cm <sup>3</sup> at 288.7 K (15.56 °C = 60 °F) |
| Melting point    | 230.35 K (–42.8 °C max.)                                    |

## 4.6 Handling of Furfuryl Alcohol

### 4.6.1 Suitability of Construction Materials for Use with Furfuryl Alcohol

Most common metals and non-metals, except rubber and neoprene, are suitable for use in equipment for handling FA. Furfuryl alcohol is a good solvent, so it will dissolve some lubricating agents. It is therefore recommended that fluorinated hydrocarbons or inorganic solid lubricants based on molybdenum sulfide or graphite should be used.

## 4.7 Safety Properties of Furfuryl Alcohol

### 4.7.1 Fire Hazard Properties of Furfuryl Alcohol

The handling of FA presents a low fire hazard because the vapor pressure of FA is low. The flammability hazard of furfuryl alcohol (Table 25) is minimal compared to that of ethyl alcohol. FA fires can be extinguished with water, in which it dissolves.

**Table 25:** Flammability properties of furfuryl alcohol.

| Property                 | Temperature                                                         |        | References |
|--------------------------|---------------------------------------------------------------------|--------|------------|
| Flash point (open cup)   | 348 K                                                               | 75 °C  |            |
| Autoignition temperature | 663 K                                                               | 390 °C | [72]       |
| Limits of flammability   | 1.8 vol.-% (at 345 K = 72 °C)<br>to 16.3 vol.-% (at 390 K = 117 °C) |        | [72]       |

#### 4.8 Toxicity of Furfuryl Alcohol

Protective clothing to be worn during the handling of FA must include goggles and gloves. FA is slowly resorbed through the skin, so splashes of FA on the skin or into the eyes must be rinsed immediately with water. Clothing or protective equipment soaked with FA must be removed immediately and washed thoroughly before reuse.

The OSHA threshold limit value TLV/TWA for 8 h/d, 5 d/week exposure is 50 ppm (200 mg/m<sup>3</sup>), but the NIOSH REL TWA is 10 ppm (40 mg/m<sup>3</sup>) with a skin notation. The NIOSH IDLH is 75 ppm.

Furfuryl alcohol vapor is a respiratory tract irritant. Extended inhalation of FA vapor causes symptoms similar to intoxication by other higher (C<sub>4</sub> to C<sub>5</sub>) alcohols [73]. The inhalation toxicity hazard of FA is relatively low due to the low vapor pressure of this compound.

Male and female rats and mice were exposed to >98% pure furfuryl alcohol by inhalation at concentrations of 0, 2, 8, or 32 ppm for 16 days, 14 weeks, or 2 years [120]. Exposure of male and female rats and male mice to furfuryl alcohol was associated with an increased incidence of non-neoplastic lesions of the nose and increased severity of nephropathy. Exposure of female mice to furfuryl alcohol was associated with increased incidences of non-neoplastic lesions of the nose and corneal degeneration.

In the very early years of liquid rocketry in the US, a mixture of furfuryl alcohol, aniline, and hydrazine was used as a hypergolic fuel in sounding rockets developed by JPL and Aerojet. The toxicity of the ternary propellant mixture was investigated in animal exposure tests [121]. Hydrazine was the most toxic constituent of this mixture.

### 5 Polyols

There are many polyfunctional alcohols, including bifunctional alcohols such as ethylene glycol and trifunctional alcohols such as glycerol. Strictly speaking, even sugar and cellulose should be listed under this heading. Polyols have not been used as fuels, but are the raw materials from which nitrate esters can be prepared by nitration with nitric acid/sulfuric acid mixtures. Properties of polyols are not included in this book because they are not useful as fuels.

## 6 Other Alcohols

Aromatic hydroxy compounds (phenols) are not discussed in the current section, which deals only with aliphatic and alicyclic hydroxy compounds.

## 7 Alcohols with Substituents in the Alkyl Group

There are many alcohols with substituents in the alkyl group, such as nitroalkanols, aminoalkanols, and azidoalkanols. In this book, these compounds are discussed in the sections relating to the groups that predominantly determine the character of these substituted alkanol compounds: nitroalkanols are considered when discussing nitro compounds, aminoalkanols when discussing amines, hydrazinoalkanols when discussing hydrazines, and azidoalkanols when discussing azides. The presence of the hydroxyl group does not substantially alter the reactivities of these substituted compounds. The hydroxyl group is the hydrophilic end of the molecule and facilitates the solubility of the molecule in water.

# Aliphatic Amines

## Introduction

*Encyclopedia of Liquid Fuels* contains three chapters on amines, the current chapter on “Aliphatic Amines,” a chapter on “Aromatic Amines,” and a very large chapter on “Heterocyclic and Heterocycloaliphatic Amines.” Amines are used as rocket fuels and as raw materials for the synthesis of other fuels and energetic compounds. A different type of amine are the nitramines described in the chapter “Nitramines.”

## 1 Aliphatic Amines

Amines are organic fuels in which one or more hydrogen atoms of ammonia are substituted by organic groups, either alkyl or aryl or heterocyclic ring groups, shown as R in the scheme below. Depending on the number of hydrogen atoms replaced by alkyl or aryl groups, we differentiate three different types of amines: primary amines, secondary amines, and tertiary amines, where one, two, or three hydrogen atoms are replaced:

|               |                |                       |                      |
|---------------|----------------|-----------------------|----------------------|
| $\text{NH}_3$ | $\text{RNH}_2$ | $\text{R}_2\text{NH}$ | $\text{R}_3\text{N}$ |
| Ammonia       | primary amine  | secondary amine       | tertiary amine       |

In addition to primary, secondary, and tertiary amines, there are multifunctional amines that contain more than one primary, secondary, or tertiary amino group in the molecule. Most of these fuels have the advantage that they are hypergolic with nitric acid and have higher boiling points than liquid ammonia, such that they can be stored as liquids at room temperature and atmospheric pressure. They are easily accessible in industrial quantities, and they are intermediates in the synthesis of many other organic compounds. Aliphatic amines, also called alkylamines, have gained renewed attention as potential replacements for more toxic hypergolic bipropellant fuels such as monomethylhydrazine (MMH) or unsymmetrical dimethylhydrazine (UDMH), which are under close scrutiny for their toxicity. Alkylamines were tested as hypergolic fuels even before MMH and UDMH came into widespread use as rocket propellants. Alkylamines are much easier to obtain than alkylhydrazines, from which they differ by one more  $\text{—NH—}$  group. Alkylamines are the raw materials from which alkylhydrazines are made. Some amines have gross formulas that are identical or similar to alkylhydrazines, but their enthalpy of formation and performance as a rocket propellant would be less than that of the hydrazine derivatives. The advantage of the alkylamines would be that they are easier to produce and less toxic. In the wake of the growing concern about hydrazine toxicity, many of the alkylamine

fuels have been reevaluated as potential alkyldiazine replacements. We list here some alkylamines that have already been used as rocket propellants, and we are also including physical properties of other alkylamines that have not yet been used as rocket fuel but which might be used as building blocks in the synthesis of other nitrogen-containing rocket fuels.

Amines are colorless liquids at room temperature, with the exception of the three methylamines, which are gases and boil below room temperature. The lower alkylamines are readily miscible with water, but those with longer alkyl groups are only sparingly soluble in water. Higher amines with long alkyl chains are wax-like solids.

Amines, in particular aliphatic amines, are easily recognized by their characteristic fishy odor, which can even be noticed in small quantities. Amines are bases, and as such they form salts with acids. Of the many possible salts, the amine nitrates and perchlorates are those with the most interest as solid propellant or explosive ingredients, and there are several sections in this chapter that describe the properties of these energetic compounds. The salts of alkylamines are normally called alkylammonium salts rather than alkylamine salts. Despite this nomenclature rule, one will often find names like “ethylamine nitrate” instead of “ethylammonium nitrate.”

The properties of alkylammonium nitrates and perchlorates are discussed at the end of each parent amine chapter. Tertiary amines form not only simple salts with acids but may also form quaternary salts if alkylated with alkyl iodides. Quaternary alkylammonium nitrates have been tested as fuels in monopropellants. They are no longer hypergolic with nitric acid or dinitrogen tetroxide, but they are soluble in nitric acid.

Multiple substitution at the ends of the alkane chain in alkylamine molecules by amino groups, hydroxyl groups, hydrazido groups, cyano groups, or azido groups will improve the water solubility; lower the freezing point; and, in the case of hydrazido, cyano, and azido groups, improve the performance as a rocket fuel. This method of producing more energetic fuels, some considered as hydrazine(s) replacements, is mostly limited to short  $C_2$  and  $C_3$  alkane chains.

Nitro groups replacing the hydrogen on the nitrogen atom in secondary aliphatic and cycloaliphatic amines, in particular secondary amines in ring structures, result in nitramines, a group of powerful explosives and solid propellant ingredients. These are described in chapter “Nitramines” of Volume 5 of this set and they are used as energetic additives in solid propellants. Replacing two hydrogens in ammonia with nitro groups leads to dinitramide,  $(NO_2)_2NH$ , which is an acid called dinitramidic (dinitraminic) acid. It is rarely used as such, but it forms salts with ammonia, hydroxylamine, hydrazine, amines, and other nitrogen bases and metals that have found use as rocket propellant ingredients. These solid salts are thermally more stable and are safer to handle than the parent acid. Dinitramide salts are described in *Encyclopedia of Oxidizers*, chapter “Dinitramide Salts.” This is a relatively recent development that has generated a lot of new information over the past 20 years.

If only one nitrogen-bound hydrogen atom is replaced by a nitro group in an alkylamine, one obtains alkylnitramines (alkylnitroamines), and the remaining hydrogen  $\text{N-H}$  is quite acidic and forms stable salts with alkali and alkaline earth metals (see chapter “Nitramines”).

Amines are stable in air and are not easily auto-oxidized, at least not as easily auto-oxidized as the alkylhydrazines. If they are exposed to air, the main concern would be the absorption of carbon dioxide from the atmosphere. Some low-volatility amines are used in the chemical industry to wash carbon dioxide and other “sour gases” from process gas streams and from natural gas. The handling of amines is relatively simple compared to handling of alkylhydrazines. Alkylamines are not very corrosive, and they can be stored and transported in most common materials of construction.

Amines are not very toxic, and many amines are naturally occurring. They will irritate the skin if accidentally spilled on skin or clothing. The vapors irritate the mucous membranes, particularly those in the eyes. In most cases, the presence of amine vapors in the air of working areas is readily recognized by the fishy odor, and the work crew is thus alerted to avoid the area and take corrective action before dangerous concentrations are attained. All amines and their vapors are combustible and form explosive mixtures with air.

Many industrial processes for alkylamine production yield a mixture of amines with different degrees of alkyl substitution. Such mixtures need to be separated by fractionated distillation in a column. If the separation by distillation is not perfect, industrial-grade amines can be contaminated by other amines. For their use as rocket fuels, the presence of minor amounts of other amines can be tolerated. Sometimes several amines are mixed deliberately to obtain low-freezing rocket-fuel mixtures.

While the free liquid amines are used as hypergolic fuels in bipropellant combinations, the solid alkylammonium nitrate salts can be used as additives in solid propellants, or (dissolved in water) as fuels in water-based monopropellants, or (as quaternary ammonium salts) dissolved in nitric acid. The most important alkylammonium salts are the nitrates. For the organization of information in this book, it was considered to combine the properties of alkylammonium salts in one separate chapter or to move them together in *Encyclopedia of Monopropellants*, under monopropellants; however, the plan was changed, and the alkylammonium and arylammonium salts are now discussed in this chapter, immediately following their parent amine free base. The same order applies to salts of amides (urea) and imides (guanidine). Nevertheless, we assemble here several summary tables with properties of alkylammonium salts. The nitrate salts are discussed first, followed by the perchlorate salts.

The energy contained in amines can be increased by including one or more  $-\text{NH}-$  groups in place of  $-\text{CH}_2-$  groups in stressed-ring cycloalkanes, thus forming azirines (three-membered rings derived from ethyleneimine) or azetanes (four-membered rings). Nitrogen can take the place of a  $-\text{CH}-$  group in bridged and caged structures.

There is a large group of heterocyclic amines that are of interest as high-nitrogen compounds for rocket propellants and gas generants either in their unprotonated state or, more frequently, in the form of their nitrate and perchlorate salts. These compounds are listed in chapter “Heterocyclic Amines” of *Encyclopedia of Liquid Fuels*.

Amides and imides are derived from ammonia by replacing one or two hydrogens with alkylcarbonyl RCO groups. The simplest amide is formamide  $\text{H}_2\text{NCHO}$ , and its close relative is urea  $(\text{H}_2\text{N})_2\text{CO}$ . Fuel values increase if the  $\text{C=O}$  group is replaced by an imine  $\text{C=NH}$  group, leading to guanidine  $(\text{H}_2\text{N})_2\text{C=NH}$ . Fuel values increase further if the amino and imino groups are replaced with hydrazino groups, as in triaminoguanidine. All of these amide and imide compounds are discussed in *Encyclopedia of Liquid Fuels*, in chapter “Amides and Imides.”

## 1.1 Nomenclature for Amines

The International Union of Pure and Applied Chemistry (IUPAC) recommendation is to name amines ( $\text{R-NH}_2$ ) for the attached alkane chain with the suffix “-amine” (e.g.,  $\text{CH}_3\text{NH}_2$  would be methanamine written in one word), but the customary naming after the alkyl group (methanamine, ethylamine) is still widely in use. If necessary, the bonding position on longer chains is inserted as a number:  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$  butan-1-amine,  $\text{CH}_3\text{CH}(\text{NH}_2)\text{CH}_3$  propan-2-amine. For secondary amines (of the form  $\text{R-NH-R}$ ), the longest carbon chain attached to the nitrogen atom becomes the primary name of the amine; the other chain is prefixed as an alkyl group with location prefix given as an *italic N*:  $\text{CH}_3\text{NHCH}_2\text{CH}_3$  is *N*-methylethanamine. Tertiary amines ( $\text{R-NR-R}$ ) are treated similarly:  $\text{CH}_3\text{CH}_2\text{N}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{CH}_3$  is *N*-ethyl-*N*-methylpropanamine, with the substituent groups in alphabetical order.

Alkylamines are sometimes called azaalkanes, in which the name given to a three-membered chain of nitrogen and carbon atoms is propane, the name for a four-membered chain of nitrogen and carbon atoms is butane, and so on. The name is always derived from the longest chain of atoms in the molecule. In this nomenclature, ethylamine would be 1-azapropane, and diethylamine would be 3-azapentane. IUPAC nomenclature calls dimethylamine “*N*-methylmethanamine.”

## 1.2 Summary Literature on Amines and Amides

Chapters on amines and amides are in most books on organic chemistry. Chapters on amines and amides are in the more popular encyclopedias, such as the *Kirk-Othmer Encyclopedia of Chemical Technology* [1–3] and Ullmann’s *Encyclopedia of Industrial Chemistry* [4, 5]. Data on amines and amides are in standard reference sources such as Houben–Weyl [6] and Beilstein [7]. There are also books written specifically for properties and applications of amines [8]. For this reason, the summary of data here can be

only partially complete in comparison to the reference works that fill an entire book shelf in the library.

Lower aliphatic amines are derivatives of ammonia with one, two, or all three of the hydrogen atoms replaced by alkyl groups of five carbons or fewer. Amines are toxic, colorless gases or liquids, are highly flammable or combustible, and have strong fishy odors. Alkylamines of lower molecular mass are water soluble and are available as aqueous solutions or in pure form. Amines react with water and acids to form alkylammonium compounds, analogous to ammonia forming ammonium salts with strong acids. The lower aliphatic amines are widely used as intermediates in the manufacturing of pharmaceutical, agricultural, textile, rubber, and plastic chemicals. Because they are readily available in industrial quantities, it is easy to divert them for use as rocket propellant ingredients.

### 1.3 Physical Properties of Amines

The following section and Table 1 contain summaries and comparative tabulations of some of the physical properties of groups of amines. The data may be repeated later in sections devoted specifically to individual amines. This is a duplication, but it is very educational to see the properties listed here first in one view to identify trends of physical properties with changes in the chemical structure of the molecule.

An excellent 69-page summary of physical properties of lower alkylamines was published as part of the National Bureau of Standards National Standard Reference Data Series [9]. This summary contains data on thermodynamic and thermophysical properties of eight primary amines, including methanamine, ethanamine, 1-propanamine, and 2-propanamine, and recommended values are given for the following properties: normal boiling point, freezing point, and triple-point temperatures; critical constants; thermodynamic properties in the solid and liquid phases;

**Table 1:** Freezing point, normal boiling point, and critical point properties of primary amines.

| Compound      | Freezing point, K              | Boiling point, K   | Critical point temperature, K | Critical point pressure, MPa | Critical point volume, cm <sup>3</sup> /mol |
|---------------|--------------------------------|--------------------|-------------------------------|------------------------------|---------------------------------------------|
| Methanamine   | 179.708<br>± 0.01 <sup>a</sup> | 266.80<br>± 0.02   | 430.7 ± 0.2                   | 7.614 ± 0.015                | 120 ± 6                                     |
| Ethanamine    | 192.62<br>± 0.05               | 289.74<br>± 0.06   | 456.2 ± 1.0                   | 5.63 ± 0.11                  | 181 ± 5                                     |
| 1-propanamine | 188.389<br>± 0.01 <sup>a</sup> | 320.370<br>± 0.002 | 497 ± 1                       | 4.72 ± 0.08                  | 228 ± 11                                    |
| 2-propanamine | 178.011<br>± 0.01 <sup>a</sup> | 304.905<br>± 0.002 | 471.9 ± 0.5                   | 4.54 ± 0.06                  | 221 ± 11                                    |

<sup>a</sup> Triple-point temperature

Data source: [9]

vapor pressure; enthalpy of vaporization; density; second virial coefficients; and enthalpy of combustion. Ideal gas thermodynamic properties were calculated using statistical mechanical methods. The boiling points were taken from a least-squares fit of the Cox equation.

### 1.3.1 Enthalpy of Formation of Amines

The heats (enthalpies) of formation are needed to calculate rocket performance when these chemicals are used as fuels with red fuming nitric acid (RFNA) or dinitrogen tetroxide (NTO) as the hypergolic oxidizer. The enthalpies of formation of aliphatic amines (e.g., azetane) in the vapor state can be calculated using *ab initio* 6-31G\* energies in place of measured data or to supplement experimental data. The results were in good agreement with those obtained experimentally and suggest that this method can be used to predict heats of formation of molecules of this class with an accuracy competitive with good-quality experiments and with probable errors of less than 1 kcal/mol [10].

Table 2 is a summary of experimentally obtained enthalpies of formation of primary amines in the liquid and vapor states.

**Table 2:** Thermodynamic data of primary amines.

| Property      | Enthalpy of formation, kJ/mol |                   |                    |
|---------------|-------------------------------|-------------------|--------------------|
| Compound      | Ideal gas                     |                   | Liquid             |
| Temperature   | 0 K                           | 298.15 K          | 298.15 K           |
| Methanamine   | $-7.82 \pm 0.41$              | $-22.53 \pm 0.41$ | $-47.27 \pm 0.40$  |
| Ethanamine    | $-26.65 \pm 0.51$             | $-47.47 \pm 0.51$ | $-74.13 \pm 0.50$  |
| 1-propanamine | $-42.36 \pm 0.39$             | $-70.10 \pm 0.39$ | $-101.47 \pm 0.38$ |
| 2-propanamine | $-56.90 \pm 0.68$             | $-83.70 \pm 0.68$ | $-112.27 \pm 0.67$ |

Data source: [9]

The enthalpies of formation of 66 nitrogen compounds in the vapor state, including many amines, were calculated by seven different molecular orbital methods and were compared to experimental results [11]. The deviations rarely exceeded 1 kcal/mol. Although it would be more practical to have the data for the liquid compounds potentially used as rocket fuels, the measured results for the vapors are listed in Table 3. The heats of vaporization of these compounds are all very similar.

**Table 3:** Enthalpy of formation of aliphatic amines.

| Compound               | Enthalpy of formation, vapor state |          |
|------------------------|------------------------------------|----------|
|                        | kJ/mol                             | kcal/mol |
| Methanamine            | −23.0                              | −5.5     |
| Dimethylamine          | −18.4                              | −4.4     |
| Trimethylamine         | −23.7                              | −5.66    |
| Ethanamine             | −47.3                              | −11.3    |
| Propan-1-amine         | −69.9                              | −16.71   |
| Propan-2-amine         | −83.7                              | −20      |
| Butan-1-amine          | −95.0                              | −22.71   |
| 2-methylpropan-2-amine | −120.0                             | −28.68   |
| 2-methylpropan-1-amine | −98.6                              | −23.57   |
| Butan-2-amine          | −106.0                             | −25.33   |

Data source: [11]

### 1.3.2 Physical Properties of Amine Salts

Salts of amines can be named using the unchanged name of the parent amine followed by the name of the anion, or the name of the amine can be changed to form a name with the suffix *ammonium* in it to indicate that they have accepted a proton and have become positively charged. This is patterned after the well-characterized ammonium  $\text{NH}_4^+$  salts. *Chemical Abstracts Service* uses a different nomenclature for salts of amines in its index.

The following section is a summary of properties of amine salts as a group. There are several sections on specific amine salts immediately following the section of their parent amine. As for the anions in these salts of interest as rocket propellants, the main interest is in nitrates, perchlorates, dinitramides, and nitroformates of these amines, mostly alkylamines. There is little information on salts of aromatic amines. The salts of heterocyclic amines have moved to a special category because many of these salts exhibit properties of ionic liquids, which are compounds of high molecular mass that are liquids at room temperature with very low vapor pressures (see *Encyclopedia of Liquid Fuels*, chapter “Ionic Liquids”).

As mentioned, *Chemical Abstracts Service* used to index alkylammonium salts under the name of the acid salt, such as “Nitric acid, methylamine salt.” When looking in the substance index, one would have to look up the name of the acid first. If one has the Chemical Abstracts Service (CAS) registry number, the CAS SciFinder search can be more specific and will usually yield the desired results. We have included the CAS registry numbers when they were available, and this will help our readers obtain additional information if needed.

### 1.3.2.1 Physical Properties of Amine Nitrates

Nitrate salts of organic amines can find various applications in rocket propellants. They are rarely used as solid propellants by themselves; most of the time they are used as additives to solid propellants or as water-soluble fuels in combination with aqueous oxidizers such as hydroxylammonium nitrate (HAN; see *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-based Monopropellants”) or ammonium dinitramide (ADN; see *Encyclopedia of Monopropellants*, chapter “Ammonium Dinitramide-Based Monopropellants”). Close to 100 different amine nitrates have been evaluated as candidate fuels for HAN for liquid gun propellants, torpedo propellants, and rocket propellants. The current chapter benefits from summaries of the properties of amine nitrates compiled by the author and other authors on various occasions when water-soluble fuels were sought as ingredients in monopropellants. Other monopropellants have been formulated by dissolving nitrates and quaternary nitrates of amines in concentrated nitric acid (see *Encyclopedia of Monopropellants*, chapter “Nitric Acid or Perchloric Acid-Based Monopropellants”). All these applications require knowledge of the physical and chemical properties of amine nitrates, in particular their water solubility, which is why we added a chapter on these compounds in this book at this location. Methods for preparation of the pure amine nitrates as precursors to rocket propellant combinations are described here. All amine nitrates (and perchlorates) in their dry state are potentially explosive, which is why their preparation and handling must be done with extreme care and with all necessary precautions. Thermal stability of amine nitrates is an important property that must be known before incorporating them in any rocket propellant. All amine nitrates are quite soluble in water, as opposed to their perchlorate counterparts, which are sometimes used to purify amines and to precipitate them as a less soluble compound. Both amine nitrates and amine perchlorates make good propellant ingredients, with the nitrates preferred if formation of hydrogen chloride in the exhaust cannot be tolerated for toxicity or environmental reasons. The nitrates are also less sensitive than the perchlorates to accidental ignition by shock or friction.

This section on amine nitrates is closely related to the section on high-nitrogen compounds. Many high-nitrogen compounds are either nitrates (listed here) or are compounds (5-aminotetrazol, aminoguanidine) that are easily converted into nitrate and perchlorate salts. Heterocyclic amines with high nitrogen content and their nitrate salts are discussed in the chapter “Heterocyclic Amines.”

The amine nitrates are discussed here in the sequence of increasing number of carbon atoms. If some of them contain the same number of carbon atoms, they are listed in the order of increasing nitrogen atoms.

To use the correct nomenclature, amine nitrates should be called alkyl- or arylammonium nitrates. Alkylammonium nitrates have also been called **aliphatic amine nitrates** and are abbreviated as AANs. If an amine contains more than one nitrogen atom that can be protonated, the number of protons added are listed in parentheses

after the name: ethylenediammonium(2+) dinitrate. *Chemical Abstracts Service* used to index them under the name of the acid salt, such as “Nitric acid, methylamine salt.” When looking in the substance index, one would have to look up the name of the acid first. If one has the CAS registry number, the CAS SciFinder search can be more specific and will usually yield the desired results. We have carried along the CAS registry numbers when they were available.

We have assembled several physical property overview tables that allow the propellant formulator to select an amine nitrate for a certain application based on its melting point, nitrogen content, or enthalpy of formation. Similar tables were assembled for amine perchlorates.

Solid amine nitrates are not typically used as rocket propellants by themselves (but they can be used as explosives without any other additives). For rocket propellant applications, they are most often dissolved in solvents, typically oxidizing solvents such as nitric acid or HAN/water or ADN/water. This chapter lists properties of dry (crystalline) organic amine (alkylammonium) nitrates only because these properties may be needed in the production and quality control of amine nitrates as propellant ingredients. The thermal decomposition and combustion of the amine nitrates by themselves (without an additional oxidizer) have been studied in an effort to explain the combustion behavior of propellants containing these chemicals. The compounds are listed in the order of increasing carbon atom content. Some alkylammonium nitrates (methylanmonium nitrate, ethylenediamine dinitrate) are used as explosive ingredients.

An important property of any alkylammonium nitrate, regardless of what application it is intended for (propellant or explosive), is its thermal stability in the solid state or in solution. Numerous studies have been conducted to derive a correlation between the chemical structure of AANs and their thermal stability. For instance, structure/decomposition relationships were developed for 26 alkylammonium nitrate salts [12]. Thermolysis studies were conducted by using rapid-scan Fourier-transform infrared spectroscopy (FTIR)/thermal profiling with heating rates of 40–250 °C/s and pressures of 6.88 kPa–6.88 MPa (1–1000 psia) of static argon. The types of products, their sequence of evolution, and the decomposition temperatures were used to develop qualitative relationships between the parent molecular structure and the thermal stability. The release of  $\text{HNO}_3$  correlates with the basicity of the parent amine [13]. A relationship between amine basicity and initial decomposition products showed a transition from acid–base chemistry at low basicity to redox chemistry at high basicity. Amines, amides, alkyl nitrates, and nitrosamines were formed as intermediates. The release of nitrosamines during use as a propellant makes these compounds a potential health risk. Similar decomposition pathways were found for all structurally related alkylammonium nitrate salts regardless of the complexity of the parent amine. However, a cycloelimination reaction was observed with the longer-chain alkyldiammonium dinitrate salts.

Tables 4 and 5 are summaries of physical and thermochemical properties of alkylammonium nitrates and similar compounds. Most of the data are for the solid salts. Because some of the nitrates, e.g., ethylammonium nitrate, melt below room temperature and are difficult to crystallize, some of the properties are given for the molten salt at 298 K. Some of the low-melting amine nitrates have found use as ionic liquids. One has to be careful to observe the physical state (solid or liquid) of the compound for which the thermodynamic data are given.

**Table 4:** Properties of open-chain alkylammonium nitrates.

| Compound                      | Heat of combustion, constant volume, liquid water, average | Heat of combustion, constant pressure | Enthalpy of formation |          | Melting point |                |
|-------------------------------|------------------------------------------------------------|---------------------------------------|-----------------------|----------|---------------|----------------|
|                               | cal/g                                                      | kcal/mol                              | kJ/mol                | kcal/mol | K             | °C             |
| Methylammonium nitrate (S)    | 2328                                                       | 218.4                                 | −337                  | −80.6    | 383.6–384.6   | 110.5–111.5    |
| Trimethylammonium nitrate (S) | 4509                                                       | 550.7                                 | −306                  | −73.1    | 428–429       | 155–156        |
| Ethylammonium nitrate (L)     | 3467                                                       | 374.5                                 | −364                  | −86.9    | 287           | 14             |

The most important property of alkylammonium nitrates is their enthalpy of formation. Literature data on enthalpies of formation of alkylammonium nitrates are listed in Table 7 for comparison to the enthalpies of formation of the parent amine. In a few instances, the enthalpy of formation of the nitrate salt may not be available, but the enthalpy of formation of the free amine is. In those cases, one can extrapolate from the enthalpy of formation of the free amine to that of its nitrate because the difference – the heat of protonation and the increment for the nitrate ion – is fairly constant. Some of these nitrate salts are ionic liquids.

**Table 7:** Comparison of enthalpies of formation of alkylammonium nitrates and their parent amines.

| Alkylamine          | Enthalpy of formation, kJ/mol | Alkylammonium nitrate         | Enthalpy of formation, kJ/mol |
|---------------------|-------------------------------|-------------------------------|-------------------------------|
| Methylamine (L)     | −47.27 ± 0.4                  | Methylammonium nitrate (S)    | −352.7                        |

<sup>a</sup> Sorted by nitrogen content

Carbon-13 spin-lattice relaxation times were measured in four alkylammonium nitrates that were candidate fuels for HAN-based monopropellants: isopropyl-, triethanol-, trimethyl-, and *n*-butyl-ammonium nitrates [26]. The relaxation mechanism in these compounds was found to be predominantly by dipolar interactions with attached protons. The relaxation times increased with temperature, as expected, but were found to be essentially independent of concentrations. Attempts were made to interpret these results in terms of ion pairing, ion clustering, molecular associations, and reorientations. This method was considered for the analysis of HAN-based monopropellants.

### 1.3.2.2 Physical Properties of Amine Perchlorates

The amine perchlorates are discussed here in the sequence of increasing number of carbon atoms. If they contain the same number of carbon atoms, they are listed in the order of increasing nitrogen atoms.

To use the correct nomenclature, amine perchlorates should be called alkylammonium perchlorates. If an amine contains more than one nitrogen atom that can be protonated, the number of protons added are listed in parentheses after the name, e.g., ethylenediammonium(2+) diperchlorate. *Chemical Abstracts Service* used to index them under the name of the acid salt, such as “Perchloric acid, methylamine salt.”

When looking in the substance index, one would have to look up the name of the acid first. If one has the CAS registry number, the CAS SciFinder search can be more specific and will yield the desired results more quickly.

We have added six physical property overview tables (Table 9 through Table 14) that allow the propellant formulator to select an amine perchlorate for a certain application based on its melting point, nitrogen content, or enthalpy of formation.

**Table 9:** Nitrogen content and oxygen balance of amine perchlorates in comparison to guanidinium perchlorates.

2-kg weight in US Bureau of Mines machine

Data source: [30]

The method used to determine the ignition temperatures in Table 13 consisted of dropping a sample into a pre-heated test tube under carbon dioxide cover gas to exclude air. Other investigators used ignition delay and isothermal rate of weight loss measurements to determine the activation energies of decomposition of several alkylammonium perchlorates [35, 36]. For instance, the ignition temperature of methylammonium perchlorate was 583 K (310 °C), and the ignition temperature of isopropylammonium perchlorate was 564 K (291 °C). The activation energy derived from isothermal rate of weight loss measurements was 167 kJ/mol (40 kcal/mol) for methylammonium perchlorate and 192 kJ/mol (46 kcal/mol) for isopropylammonium perchlorate. Proton transfer dissociation is the first step in the decomposition of these salts. The HClO<sub>4</sub> thus formed can decompose into chlorine oxides that will accelerate the decompo-

sition and lead to ignition. Alkylammonium perchlorates might have the same gross elemental composition as ammonium perchlorate (AP)/binder combinations, but the decomposition behavior is quite different from that of composite propellants.

A book on the structure and stability of salts of halogen oxyacids contains chapters on the preparation and thermal stability of organic amine perchlorates [37].

### 1.3.2.3 Quaternary Ammonium Salts

Quaternary ammonium salts were used by J. D. Clark in his (in)famous CAVEA monopropellants. A good anecdotal description of the history of the development of CAVEA monopropellants and impressive photos of the results of monopropellant explosions are contained in Clark's book *Ignition!* [38], from which the current book borrowed the preface quote by I. Asimov about the mental state of rocket propellant chemists, including the author of the book at hand.

### 1.3.2.4 Autoignition of Aliphatic Amines

It is unlikely that flammable mixtures of aliphatic amines and oxygen would form under normal conditions of use of alkylamines, but the auto-ignition temperatures of stoichiometric oxygen/amine vapor mixtures at below atmospheric pressures were measured in Pyrex vessels [39]. The amines tested included the primary, secondary, and tertiary methylamines and ethylamines. The ease of oxidation decreased in the order tertiary > secondary > primary amines. For stoichiometric mixtures, a correlation was established between the auto-ignition temperature and the pressure in the vessel. For instance, for a mixture containing 16.7% by volume triethylamine in oxygen at 26.7 kPa (200 mm Hg), the first explosion would take place at 527 K (254 °C). Leaner mixtures would only ignite at higher temperatures. Oxygen/ethylamine mixtures auto-ignited only at temperatures higher than for oxygen/triethylamine mixtures.

## 2 Aliphatic Amines with One Nitrogen Atom in the Molecule

### 2.1 Methylamines

Methylamines are the lowest members of the family of amine fuels:

|                                                                               |                            |
|-------------------------------------------------------------------------------|----------------------------|
| Methylamine (sometimes called monomethylamine or aminomethane or methanamine) | $\text{CH}_3\text{NH}_2$   |
| Dimethylamine                                                                 | $(\text{CH}_3)_2\text{NH}$ |
| Trimethylamine                                                                | $(\text{CH}_3)_3\text{N}$  |

Methylamines are derivatives of ammonia in which one, two, or all three of the hydrogen atoms have been replaced by methyl groups [2]. Methylamines are colorless gases or compressed liquids, are highly flammable, and have very strong fishy or ammonia-

like odors. They are water soluble and are available as either aqueous solutions or in pure form. Due to their high reactivity, there are numerous industrial applications for methylamines as raw materials for the synthesis of solvents, crop-protection agents, pharmaceuticals, surfactants, rubber chemicals, ion-exchange resins, explosives, animal feed, building blocks for the paper industry, and water treatment materials.

Of all the alkylamines, the methylamines are the ones most readily accessible through synthesis, starting with natural gas that is converted to ammonia and methanol. They can be obtained by reaction of ammonia with methanol on the surface of catalysts. This should make them good rocket fuels, except for the shortcoming that they are not hypergolic with nitric acid without a hypergolizing additive such as an alkyldiazine or an alkali metal.

The primary, secondary, and tertiary methylamines are all vapors at room temperature and atmospheric pressure. All three methylamines can be considered storable fuels. They can be stored indefinitely as liquids at room temperature under their own vapor pressure, a moderate vapor pressure that makes them still easy to handle. They are commonly shipped and stored in steel cylinders with pressure-relief valves or burst discs. The vapor pressures of methylamine, dimethylamine, and trimethylamine at room temperature are 2.79, 159, and 186 kPa (2100, 1200, and 1400 mm Hg), respectively.

Only a few investigations of methylamines as rocket fuels have been reported. They can be used in mixtures with hydrazine to lower the freezing point of hydrazine or to stabilize hydrazine to the point where it can be used as a regenerative coolant in bipropellant engines. The gross composition of such mixtures would be similar to that of MMH or UDMH, but the performance would not be as good. Methylamine is a precursor for the synthesis of MMH, and dimethylamine is a precursor for the synthesis of UDMH.

### 2.1.1 Preparation of Methylamines

Methylamines can be prepared by the reaction of ammonia with methanol under pressure in the presence of aluminosilicate catalysts.

In this way, an estimated 115000 tons of methylamine were produced in 2005. Dimethylamine and trimethylamine are inevitable by-products of this process, and it is difficult to stop the process at the stage of the monomethylamine. The reaction conditions and reactant ratios determine the ratio of the three products. The product most favored by the reaction kinetics is trimethylamine.

Monomethylamine, dimethylamine, and trimethylamine are major industrial chemical intermediates. Generally, these compounds are prepared by reaction of methanol and ammonia over a dehydration catalyst such as silica alumina. While thermodynamics favors trimethylamine formation, market demand is for dimethyl-

amine. This has led to the development of highly dimethylamine-selective zeolite-based catalysts [40].

### 2.1.2 Physical Properties of Methylamines

Physical properties of methylamines are listed in Table 15.

**Table 15:** Physical properties of methylamines.

The vapor pressure of methylamine can be calculated from the Antoine equation

$$\ln p_{\text{sat}} = 6.4613 - 1010.93/(T - 39.94)$$

where  $p_{\text{sat}}$  is the saturation pressure in kPa and  $T$  is the temperature in kelvin, valid for the pressure range 20–200 kPa. A similar Antoine equation allows us to calculate the vapor pressure for the temperature range from 190 to 266.9 K from the equation

$$\log p_v = 4.520 - [1034.977/(T - 37.574)]$$

where  $p_v$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

Viscosity data for liquid methylamine have been obtained in the temperature range of 203 to 263 K (−70 to −10°C) using an Ubbelohde viscometer [41]. The results were compared with existing data, and all the data were fitted to the Fulcher (Tammann–Hesse) equation by the method of least squares. The significance of the

values of  $T_0$  in this equation for these and other associated liquids was considered. The methylamine viscosity data in Table 16 below can be expressed by a Fulcher-type equation

$$\log \eta = -1.3634 + 126.389/(T - 102.886)$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The viscosity calculated with the equation at 298 K (outside the valid range) is 0.19 cPs. The accuracy of this equation is  $\pm 0.32\%$ .

**Table 16:** Viscosity of liquid methylamine at various temperatures.

| Temperature |     | Viscosity |
|-------------|-----|-----------|
| K           | °C  | cPs       |
| 203.1       | -70 | 0.802     |
| 208.1       | -65 | 0.681     |
| 213.1       | -60 | 0.604     |
| 218.1       | -55 | 0.54      |
| 223.1       | -50 | 0.484     |
| 228.1       | -45 | 0.443     |
| 233.1       | -40 | 0.404     |
| 238.1       | -35 | 0.374     |
| 243.1       | -30 | 0.348     |
| 248.1       | -25 | 0.323     |
| 253.1       | -20 | 0.301     |
| 258.1       | -15 | 0.28      |
| 263.1       | -10 | 0.266     |

Data source: [41]

Later measurements extended the range of temperatures from  $-10$  to  $+29.3^\circ\text{C}$  [42]. The raw data are summarized in Table 17 and can be expressed by the Fulcher-type equation

$$\log \eta = 1.635 + 203.2(T - 69.87)$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin.

The viscosity of liquid dimethylamine at 298 K is  $0.000232 \text{ kg m}^{-1} \text{ s}^{-1}$ . The surface tension of dimethylamine at 298 K is  $0.02634 \text{ N/m}$ .

A fuel mixture of methylamine with hydrazine and aniline has been evaluated as a hypergolic fuel for use with white fuming nitric acid (WFNA) or RFNA. Methylamines are miscible with hydrazine and could be used as a substitute for MMH or UDMH in making hydrazine blends if there were to be a shortage of MMH or UDMH [43].

Thermodynamic properties of methylamines are summarized in Table 18. See also [44, 45].

**Table 17:** Viscosity of liquid methylamine.

| Temperature |       |       | Temperature |       |       | Temperature |       |       |

### 2.1.3 Chemical Properties of Methylamines

Methylamines serve as intermediates in the production of methylhydrazines by the Raschig process. The assay and the analysis for contaminants in methylamines are best performed using gas chromatography.

### 2.1.4 Handling of Methylamines

The transfer of methylamines between transport and storage containers should be done under pressure. If the compounds are chilled to be transferred at atmospheric pressure, one must avoid exposure to air because moisture and carbon dioxide will condense into the cold liquids.

The transfer lines must be hermetically sealed to prevent escape of amine vapors that would endanger bystanding personnel and which may form flammable and explosive mixtures in air. All containers should be grounded to prevent buildup of electrostatic charges.

### 2.1.5 Toxicity of Methylamines

The presence of methylamine vapors in the air is easily recognized by their penetrant fishy odor. At very high concentrations above 100–500 parts per million (ppm), the odor is hard to differentiate from that of ammonia. Airborne concentrations of methylamines at the workplace should not exceed 225 ppm. At concentrations greater than 100 ppm, the strong eye and respiratory irritation will force the workers to leave the area and seek a safe place with fresh air. There are no reported poisoning incidents due to methylamine inhalation.

Methylamines and their concentrated aqueous solutions are strongly irritating to the skin and will cause chemical burns. Methylamines and their concentrated aqueous solutions spilled into eyes are dangerously corrosive and may cause blindness, similar to ammonia solutions. The eyes must be washed with large amounts of water immediately. If methylamines are spilled on clothing, the clothing must be removed and the affected skin parts rinsed with water, neutralized with 1% acetic acid (vinegar), and again rinsed with water.

The toxicology of dimethylamine animal exposure test results is summarized in Table 19.

The established legal limits for worker exposure to methylamines at the workplace are summarized in Table 20.

Additional toxicity information on dimethylamine is contained in [46–48], and similar information for trimethylamine is in [49]. The LC50 for dimethylamine is 4700 ppm. A level of distinct odor awareness (LOA) of 0.53 ppm was calculated for dimethylamine. A very detailed summary of toxicity information for dimethylamine was compiled in [50].

In a non-cancer inhalation chronic toxicity assessment of diethylamine, rats were exposed to 0, 31, 62.5, and 125 ppm diethylamine and mice to 0, 16, 31, and 62.5 ppm

**Table 19:** Toxicity of dimethylamine based on animal exposure tests.

| Compound name | Toxicity | Animal               | Mode of administration | Result     |
|---------------|----------|----------------------|------------------------|------------|
| Dimethylamine | LD50     | Mouse                | Intraperitoneal        | 736 mg/kg  |
|               | LD50     | Mouse                | Oral                   | 316 mg/kg  |
|               | LD50     | Rat                  | Oral                   | 698 mg/kg  |
|               | LD50     | Rat                  | Dermal                 | 3900 mg/kg |
|               | LD50     | Guinea pig or rabbit | Oral                   | 240 mg/kg  |

diethylamine for 6 h/d, 5 d/week for 105 weeks [51]. Mice were slightly more sensitive than rats. The critical effect identified in mice was hyperostosis in the turbinates, although diethylamine caused a number of other non-neoplastic lesions. The chronic reference value for diethylamine is 11 parts per billion (ppb; 33 µg/m<sup>3</sup>).

### 2.1.6 Flammability of Methylamines

Vapors of methylamines are flammable in air. Flammability and ignition characteristics are summarized in Table 21. The accidental ignition of dimethylamine vapors has been the cause of an accident in the production of UDMH [52].

**Table 21:** Flammability and ignition of methylamines.

|                                                |       | Methylamine | Dimethylamine  | Trimethylamine |
|------------------------------------------------|-------|-------------|----------------|----------------|

## 2.2 Methylammonium Salts

Methylammonium nitrates are useful energetic additives because with the short alkyl group they do not require as much oxygen to achieve complete combustion as the higher alkylammonium nitrates. The relative thermal stability of alkylammonium salts was studied as a function of the type and numbers of alkyl (or aryl) substituents [55]. It was attempted to explain the thermal stability of substituted ammonium cations paired with nitrate anions. The basicity of the central nitrogen atom has an effect on the thermal stability of the nitrate salts formed. Although the thermal stability of alkylammonium nitrate salts differs substantially from one salt to the next, there may be a common mechanism by which these salts decompose when they are heated. Thermographic analysis coupled with mass spectrometry of the off-gassing products showed that the thermal stability (both endotherms and exotherms) decreases with increasing number of methyl groups in the molecule, except that the quaternary tetramethylammonium nitrate was exceptionally stable due to the symmetry of the cation formed. Figure 1 shows the temperature differences recorded during differential thermal analysis (DTA) of methylammonium nitrate, dimethylammonium nitrate, trimethylammonium nitrate, dimethylammonium perchlorate, and trimethyl ammonium perchlorate. It is unusual to crowd that many thermogram traces into one image, but this display method allows easy comparison of the thermal stability of these five compounds. The terminal exotherms of methylammonium nitrate and dimethylammonium nitrate observed in air were replaced by endotherms when the test was performed under reduced pressure at 67 Pa (0.5 mm Hg) instead of air.

A common first step in the thermal decomposition of alkylammonium nitrates is proton transfer. However, in the case of alkylammonium perchlorates, the first step of thermolysis is formation of methyl carbonium  $\text{CH}_3^+$  ions.

**Figure 1:** Differential thermal analysis traces of methyl-, dimethyl-, and trimethylammonium nitrates and perchlorates at 0.5 mm Hg pressure (Reproduced and modified from [55].)

### 2.2.1 Methylammonium Nitrates

Methylammonium nitrate, also known as monomethylammonium nitrate, methylamine nitrate, monomethylamine nitrate; methanamine, nitrate (1:1); MEAN,  $\text{H}_3\text{CN}^+\text{H}_3\text{NO}_3^-$ ,  $\text{C}_1\text{H}_6\text{N}_2\text{O}_3$ , CAS RN [22113-87-7], can be prepared by neutralization of methylamine solutions with dilute nitric acid. Methylammonium nitrate is an ingredient in commercial explosives, such as Tovex<sup>®</sup>.

#### 2.2.1.1 Physical Properties of Methylammonium Nitrate

Physical properties of MEAN are summarized in Table 22. Methylammonium nitrate forms prismatic crystals, with a melting point of 382–384 K (109–111°C), which are very hygroscopic. Methylammonium nitrate is considerably more hygroscopic than ammonium nitrate. When exposed to 50% relative humidity, it absorbs 100% by mass in 21 d.

Differential scanning calorimetry (DSC) analysis of MEAN crystals has shown an endothermic solid-phase transition at 359 K (86°C), and the onset of exothermic decomposition is at 533 K (260°C) [45, 56]. Mixtures of MEAN with ammonium nitrate

(AN), sodium nitrate, or calcium nitrate form low-melting eutectics that can be used as castable explosives.

Methylammonium nitrate with hydroxylammonium nitrate forms a low-melting ionic liquid [57].

**Table 22:** Physical properties of methylammonium nitrate.

| Property                     | Temperature in K | SI units                | Other units     | References                |

### Thermodynamic Properties of Methylammonium Nitrate

The thermodynamic properties of alkylammonium nitrate are of interest to calculate theoretical performance in rocket engines and to correlate the heat of neutralization with the ignition delay in hypergolic bipropellant ignition tests. The difference between the measured heat of formation of methylamines and ethylamines and their nitrates is summarized in Table 23. This number is a composite of the heat of formation of nitric acid and the heat of neutralization.

The heat of neutralization decreases with increasing alkyl substitution in the ammonia molecule. The average difference in the heats of formation of the five salts in Table 23 is  $-122 \pm 22$  J. Methylamine seems to be “outside the family.” If methylamine were omitted, the average difference would be  $107 \pm 7$  J. Many of the alkylammonium nitrates have been evaluated as propellant or explosive ingredients, but the necessary

**Table 23:** Heat of neutralization of alkylamines plus enthalpy of formation of nitric acid.

| Amine          | Difference in enthalpy of formation, J/mol of amine |
|----------------|-----------------------------------------------------|
| Methylamine    | –132.8                                              |
| Dimethylamine  | –114.8                                              |
| Trimethylamine | –89.7                                               |
| Ethylamine     | –118.5                                              |
| Triethylamine  | –105.1                                              |

Data source: [58]

enthalpies of formation (or the heats of combustion) were not always available for performing theoretical performance calculations for specific impulse in a rocket or impetus in a cannon. In most cases, the enthalpies of the free amine were available from the literature. So if one could apply a conversion factor (addition, difference) to the enthalpy of the free (liquid) amine to obtain the enthalpy of formation of the solid amine nitrate, that would be a great help. With some precaution, a similar factor might even be applied to alkylhydrazines to obtain the heats of formation of hydrazinium salts. Table 24 is a summary of enthalpies of formation of various amine nitrates that came from literature sources or were extrapolated using application of a conversion addition. The process would be more accurate if different, separate additions were applied for primary, secondary, and tertiary amines.

**Table 24:** Enthalpies of formation of alkylammonium nitrates.

| Compound                                  | Formula                                                              | Enthalpy of formation, kJ/mol | Note <sup>a</sup> |

<sup>a</sup> Source of data as referenced by [58]: 1,2 = from the literature; 3 = calculated by applying constant nitrate difference (-117 J/mol) to known heat of formation of free amine in the liquid state; 4 = both heat of free amine and nitrate calculated by Freedman

Although MEAN is (was) widely used throughout the industry, literature data for its enthalpy of formation vary widely, as shown in Table 25. An additivity density functional theory (DFT) method predicted an enthalpy of formation of -3.40 kJ/g for crystalline MEAN, and the measured value was -3.75 kJ/g [59]. The heat of combustion at constant volume of MEAN is 901 kJ/mol = 215.4 kcal/mol [60].

**Table 25:** Enthalpy of formation of methylammonium nitrate.

| Enthalpy of formation |          |       |        | References |
|-----------------------|----------|-------|--------|------------|
| cal/g                 | kcal/mol | J/g   | kJ/mol |            |
| –900                  | –84.7    | –3767 | –354.4 | [58]       |
| –896                  | –84.3    | –3750 | –352.7 | [15]       |

| –856                  | –80.6    | –3582 | –337   | [14]       |

Note: Molecular mass: 94.07 g/mol = 10.6304 mol/kg

### Molecular Structure of Methylammonium Nitrate

The crystal and molecular structure of MEAN is orthorhombic, space group *Pcmm*,  $a = 6.414(4)$  Å,  $b = 6.581(4)$  Å, and  $c = 10.412(3)$  Å,  $Z = 4$  [61]. Hydrogen bonds exist between the cations and anions. Differential scanning calorimetry and vibrational studies indicated phase changes occurring at 355 and 245 K.

#### 2.2.1.2 Chemical Properties of Methylammonium Nitrate

The oxygen balance of MEAN is –34%, and the nitrogen content is 29.78%. As the salt of a strong acid and a weak base, MEAN hydrolyzes to an acidic (and therefore corrosive) solution when dissolved in water.

### Thermal Stability of Methylammonium Nitrate

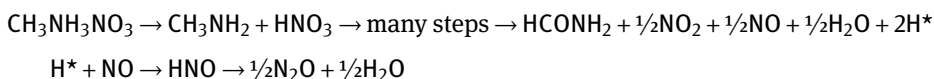

The thermal decomposition of the mono-, di-, and trimethyl-ammonium nitrates has been studied using DTA, thermogravimetric analysis (TGA), and mass spectral analysis (Figure 1) [56]. The decomposition temperature, the onset of exotherm, of these compounds at atmospheric pressure decreased in the order  $\text{CH}_3\text{NH}_3\text{NO}_3 > (\text{CH}_3)_2\text{NH}_2\text{NO}_3 > (\text{CH}_3)_3\text{NHNO}_3$ . The activation energies have been determined employing isothermal decomposition technique. Mass spectrometric investigation showed that the extent of decomposition increased with increasing substitution on the nitrogen atom, which can be explained by different C–N bond strengths.

DTA and mass spectrometry (MS) tests indicated that MEAN dissociates on heating to form methylamine and nitric acid, which then react further or decompose to form other compounds, including nitrogen oxides and nitrous acid [62]. Reaction products of nitrous acid and methylamine, such as nitromethane, are indicated in the mass spectra fragmentation profiles ( $m/e$  value of 61). A trace of hydrazoic acid was also detected. Methylamine, one of the dissociation products, is a flammable gas, and in the presence of nitrogen dioxide the auto-ignition temperature is lowered to 573 K (300 °C) or less. Rust or copper contamination will lower the auto-ignition temperature of the molten salt. Preventing acid buildup and rust formation is important for the safe handling and transport of monomethylamine nitrate.

Several types of experiments have indicated that MEAN dissociates into nitric acid and methylamine prior to decomposition. The major products at 473 K (200 °C) were H<sub>2</sub>O, NO<sub>2</sub>, NO, and N<sub>2</sub>. Other components present in smaller quantities were CH<sub>3</sub>NH<sub>2</sub>, CO, and N<sub>2</sub>O. At 573 K (300 °C) the formation of N<sub>2</sub>, NO, CO<sub>2</sub>, and N<sub>2</sub>O increased relative to NO<sub>2</sub>, CO, and H<sub>2</sub>O, and CH<sub>3</sub>NH<sub>2</sub> was no longer detectable.

The thermal reactivities of MEAN with oxidizing agents such as other nitrates, nitrites, perchlorates, and chlorates have been studied using DTA [63]. There were no oxidation–reduction reactions between MEAN and oxidizing agents, but the formation of unstable salts of methylamine was the most likely cause of the incompatibilities of the mixtures of MEAN and the other salts. Methylammonium nitrite, which is unstable even at room temperature, was formed by the reaction of MEAN and NaNO<sub>2</sub> or KNO<sub>2</sub>. Its presence as a contaminant in MEAN must be avoided. Similarly, methylammonium chlorate, formed from MEAN and NaClO<sub>3</sub> or KClO<sub>3</sub>, decomposed explosively at much lower temperature than MEAN or methylammonium perchlorate (MAP). Its presence as a contaminant in MAP must be avoided.

Another study of thermal decomposition of alkylammonium nitrates [12, 13] confirmed the dissociation of MEAN into nitric acid and methylamine, and a reaction mechanism was proposed as follows:

At higher temperatures the gaseous products detected by FTIR were CO<sub>2</sub>, N<sub>2</sub>O, HCN, NO, CO, and trace amounts of NH<sub>3</sub> and CH<sub>4</sub>. Hydrogen cyanide and methane make an abrupt appearance as soon as the temperature is increased from 513 to 553 K (240 to 280 °C).

The thermal decomposition of MEAN and the postulated intermediacy of methylnitramine, CH<sub>3</sub>NHNO<sub>2</sub>, or *aci*-methylnitramide in the decomposition of MEAN were reinvestigated [64]. If methylnitramine is an intermediate, the weakest bond (N–NO<sub>2</sub>) should break first.

The thermal decomposition of MEAN was studied because it is used in commercial water-gel explosives [65]. Because of its hygroscopic nature, MEAN crystals were placed in open pans in the differential scanning calorimeter and were first temperature-cycled to eliminate water to obtain accurate values for the solid–solid transition and the melting point. The exothermic behavior of MEAN was studied by isothermal and non-isothermal DSC in hermetic pans, by TGA, and also by accelerating rate calorimetry (ARC). The results were compared to those for AN and literature data on MEAN. Extrapolation of DSC data on the onset temperature of the exotherm yielded reasonable agreement with large-scale ARC tests, so the onset temperature can be considered a practical parameter for hazard analysis of these types of energetic materials.

Methylammonium nitrate is used for slurry explosives. It has been transported in the molten state, but several explosions of tank cars containing molten MEAN solutions have occurred in transit.

### 2.2.1.3 Safety Properties of Methylammonium Nitrate

For many decades, tank cars with molten MEAN were shipped across the United States. That changed when, on 6 August 1974, a tank car loaded with MEAN exploded while being pushed and bumped in a railroad switching yard in Wenatchee, Washington, killing two persons and injuring 66 others [66]:

Three tank-cars, owned by the Burlington Northern Railway (BNR), were en route from an E. I. du Pont de Nemours and Company chemical plant in Biwabik, Minnesota, to the company's explosives manufacturing facility in Dupont, Pierce County, Washington. The blast left a crater in the middle of the rail yard 80 feet long, 60 feet wide, and 35 feet deep, and all but leveled an area a half-mile-wide. The cars, double-walled with an inner stainless steel tank encased by a 10-inches of fiberglass insulation and an outer steel shell, each contained 10000 gallons of PR-M (monomethylamine nitrate), the company's designation for a sensitizing agent used to make Tovex, a new type of explosive gel used by the mining industry. The PR-M was shipped in an 85 percent aqueous solution, keeping the chemical stable and supposedly safe. The Department of Transportation (DOT) classified the product in solution as a 'flammable solid' whereas dry PR-M crystals were classified as a 'Class A explosive,' the same as dynamite. DuPont had been shipping the semi-solid chemical, under a special permit issued by DOT's Office of Hazardous Material, since 1968.

A few years later, on 4 July 1976, a storage tank with 60000 pounds of MEAN detonated at DuPont's Potomac River Works. Though there was no loss of life, there were many injuries and substantial loss of property. As a result, within 2 years DuPont moved out of the water-gel explosives business, but Tovex® is still used in other countries.

### 2.2.1.4 Explosive Performance of Methylammonium Nitrate

In the lead block test, MEAN gave an increase in the volume of the cavity of  $325 \text{ cm}^3/10 \text{ g}$ .

Tovex (other trade names are Trenchrite, Seismogel, and Seismopac) is a cap-sensitive water-gel explosive composed of ammonium nitrate and MEAN that has several advantages over traditional nitroglycerine/diatomaceous earth dynamite, including lower toxicity and safer manufacture, transport, and storage. Tovex is a 50/50 aqueous solution of AN and MEAN with gelling agents and stabilizers and sensitizers. It does not need a booster charge but will often be initiated by a network of strings of Detacord. It has thus almost entirely replaced dynamite. Tovex is used in quarries and by many international oil companies for seismic exploration.

### 2.2.1.5 Other Applications for Methylammonium Nitrates

An experimental liquid gun propellant, LP1776, was similar to NOS365, except IPAN had been replaced by trimethylammonium nitrate.

The U.S. Air Force Research Laboratory developed three monopropellants, RK-124A, RK-124B, and RK-916, that contained MEAN besides AN, hydrazine mononitrate (HN), and water.

Solutions of MEAN in hydrazine, for instance a 50%  $[\text{CH}_3\text{NH}_3]\text{NO}_3$  solution in hydrazine [67] or solutions of MEAN in mixtures of hydrazine and UDMH, were proposed as monopropellants or as hypergolic fuels for use with RFNA, WFNA, or fluorine as the oxidizer [68].

### 2.2.2 Alkylammonium Perchlorates

Substituted amine perchlorates have generated considerable interest since they can be used as auxiliary oxidizers and burning rate additives in composite solid propellants. However, these substituted perchlorates are quite sensitive to explosive stimuli such as impact and friction, thus restricting their use in practical propellant systems. It was shown that MAP is the most sensitive to impact and that the relative thermal stability increases with progressive substitution. The inductive effect of the methyl group is supposed to play a role in the thermal stabilization by increasing the electron density on the nitrogen, thereby making the proton transfer process more difficult. Activation energies increase with substitution up to trimethylammonium perchlorate. Tetramethylammonium perchlorate showed a different trend. This has been explained on the basis of the proton transfer dissociation mechanism, which cannot take place with four methyl substituents on nitrogen.

#### 2.2.2.1 Methylammonium Perchlorate

Methylammonium perchlorate, is also known as monomethylammonium perchlorate, methylamine perchlorate, methanamine perchlorate, aminomethane perchlorate,  $\text{H}_3\text{CN}^+\text{H}_3\text{NO}_3^-$ , MeAP, MAP, CAS RN [15875-44-2].

Many alkyl- and aryl-substituted ammonium perchlorates have been evaluated as oxidizers in solid propellants. These compounds have been reported to sublime and decompose at lower temperatures than the nitrates and were found to explode readily at higher temperatures, which is a safety hazard. These perchlorate salts are generally much more violent in their explosive behavior than nitrate salts. Some of them will explode in response to only slight shock or friction. Alkylammonium perchlorates can be prepared by reacting  $\text{HClO}_4$  with the appropriate amine in aqueous solution. Monomethylammonium perchlorate (MAP), dimethylammonium perchlorate (DMAP), and trimethylammonium perchlorate (TMAP) were prepared by titrating aqueous solutions of methyl-substituted amines with 70%  $\text{HClO}_4$  using methyl red as the indicator. The water was slowly evaporated until incipient crystallization.

MAP can be prepared by the **slow** addition of 24 mass-% aqueous methylamine solution to 71%  $\text{HClO}_4$  with stirring and cooling [69, 70]. MAP was recrystallized twice from ethanol. The low yield of 28% is due to the high solubility of MAP in water and ethanol. MAP can also be recrystallized from 2-propanol or from EtOH/chloroform 1 : 1.

MAP can also be prepared by the neutralization of an alcoholic solution of methylamine with aqueous perchloric acid, by bubbling methylamine gas into 70% perchloric acid and bubbling methylamine gas into perchloric acid in ethanol. Another way to prepare MAP is by reacting methylammonium chloride and other methylammonium salts with perchloric acid and driving off the hydrogen chloride.

But the safest and most convenient method was found to be the first one mentioned above, the **slow** addition of aqueous 24% methylamine solution to 71% perchloric acid.

### 2.2.2.2 Physical Properties of Methylammonium Perchlorate

The physical properties of MAP are summarized in Table 26.

**Table 26:** Physical properties of mono-, di-, tri-, and tetramethylammonium perchlorates.

| Compound name                          | Property                                     | SI units                       | At temperature, K | Other units | References |
|----------------------------------------|----------------------------------------------|--------------------------------|-------------------|-------------|------------|

| <b>Tetramethylammonium perchlorate</b> |                                              |                                |                   |             |            |
|                                        | Density                                      | 1.35 g/cm <sup>3</sup>         | 298               | 25 °C       | [70, 71]   |

### 2.2.2.3 Crystal Structure and Phase Changes of Methylammonium Perchlorate

Methylammonium perchlorate undergoes several phase changes prior to melting at 528 K (255 °C). At room temperature it exists in the monoclinic/triclinic crystal form, above 321 K (48 °C) it exists in the tetragonal crystal form, and above 451 K (178 °C) it converts to a cubic crystal form. A crystallographic phase change at a little above 323 K causes a quite significant decrease in density. It decomposes slowly above the melting

point and deflagrates at 593 K (320 °C). The di- and trimethylammonium perchlorates also exist in several phases and undergo phase transitions before melting.

The thermal transformations that take place in solid methyl-substituted ammonium perchlorates were studied using high-temperature X-ray diffraction (XRD) and DTA [33, 34]. Ammonium perchlorate and tetramethylammonium perchlorate  $\text{N}(\text{CH}_3)_4\text{ClO}_4$  undergo one enantiomorphic phase transition (with decomposition), at 513 and 613 K (240 and 340 °C), respectively. This I-II transition is due to the beginning of the free rotation of the  $\text{ClO}_4^-$  ions. The free rotation of cations begins below room temperature. If the symmetry of the cation is lowered by having both methyl groups and hydrogen atoms arranged around the nitrogen, there is an additional enantiomorphic phase transition. This II-III transformation has been ascribed to the rotation of the cations, which have different moments of inertia. The properties of MAP and other amine perchlorates are summarized in Table 26.

The crystal structure of MAP is space group  $P2_1/n$ , and the cell parameters are  $a = 10.59 \text{ \AA}$ ,  $b = 7.67 \text{ \AA}$ ,  $c = 12.87 \text{ \AA}$ , and  $\beta = 101^\circ 26'$ ,  $Z = 2$  [73].

DTA of MAP revealed endothermic transitions from monoclinic to tetragonal at 322 K (49 °C), from tetragonal to cubic at 452 K (179 °C), melting at 527 K (254 °C), and ignition at 603 K (330 °C) [72].

The molecular structure of MAP can be clarified by selectively replacing hydrogen  $^1\text{H}$  in either the methyl group or the amino group with deuterium and measuring the nuclear magnetic resonance (NMR) spectra [74]. DSC data, the temperature dependence of  $^1\text{H}$  and D NMR line-shapes, and the spin-lattice relaxation times for  $\text{H}_3\text{CNH}_3\text{ClO}_4$ ,  $\text{D}_3\text{CNH}_3\text{ClO}_4$ , and  $\text{H}_3\text{CND}_3\text{ClO}_4$  confirmed the existence of three different phase modifications in  $\text{H}_3\text{CNH}_3\text{ClO}_4$  and its selectively deuterated analogs. In addition, they were used to identify the molecular motions occurring in the phases and to determine their activation parameters. In the low-temperature phase III, stable below 320 K, the  $\text{CH}_3$  and  $\text{NH}_3$  groups reorient themselves about their three-fold symmetry axes with different frequencies. In the intermediate-temperature phase II, at 320–451 K for  $\text{H}_3\text{CNH}_3\text{ClO}_4$  and  $\text{CD}_3\text{NH}_3\text{ClO}_4$  and 320 and 437 K for  $\text{H}_3\text{CND}_3\text{ClO}_4$ , the  $\text{H}_3\text{CN}^+\text{H}_3$  ions reorient themselves about an axis inclined at an angle of  $18^\circ$  to the C3 axis. In phase I, the  $\text{H}_3\text{CN}^+\text{H}_3$  ions undergo isotropic motion along with translational diffusion between different sites of the cubic unit cell.

A  $^{14}\text{N}$  and  $^{35}\text{Cl}$  double-resonance study of MAP showed that, contrary to the high-temperature phase transition being due to a change of molecular motion of the methylammonium cations, the low-temperature phase transition is triggered by a change of molecular dynamics of the perchlorate anions [75]. This could not be discovered without measuring the Cl quadrupole frequency of  $\text{ClO}_4^-$  ions in the solid state.

Static and magic-angle spinning (MAS)  $^{35}\text{Cl}$  NMR data of  $\text{ClO}_4^-$  ions in the low-, intermediate-, and high-temperature phases of  $\text{H}_3\text{CNH}_2^+\text{ClO}_4^-$  (MAP),  $(\text{H}_3\text{C})_2\text{NH}^+\text{ClO}_4^-$ , and  $(\text{H}_3\text{C})_3\text{N}^+\text{ClO}_4^-$  showed that solid–solid phase transitions are interrelated with the motional state of the  $\text{ClO}_4^-$  ions [76]. In the low-temperature phase III of  $(\text{H}_3\text{C})_3\text{N}^+\text{ClO}_4^-$  there is an anisotropic motion of the  $\text{ClO}_4^-$  ions with

a constant quadrupole frequency of 185 kHz and an increasing value of the asymmetry parameter when approaching phase transition III→II. The activation energy for this motion is 44.3 kJ/mol. At the transition III→II, the  $\text{ClO}_4^-$  ions gain orientational degrees of freedom manifested by the change of the quadrupole frequency to 159 kHz. In phase II the  $\text{ClO}_4^-$  ions start rotating, overcoming an energy barrier of 40.7 kJ/mol. In the low-temperature phase III of  $(\text{H}_3\text{C})_2\text{NH}^+\text{ClO}_4^-$  there are rigid  $\text{ClO}_4^-$  ions. At the phase transition III→II, the  $\text{ClO}_4^-$  ions gain considerable motional freedom, indicated by lowering the quadrupole frequency to 119 kHz, due to an anisotropic motion. In the high-temperature phase I, the anions undergo isotropic motion with an activation energy of 11.9 kJ/mol. The low-temperature phase III of MAP is characterized by rigid  $\text{ClO}_4^-$  ions. At the transition III→II, the  $\text{ClO}_4^-$  ions gain considerable motional freedom and undergo an axial motion in phase II. The motional behavior of the anions along with NMR data for the cations suggest that the low-temperature ordering of the ions in phase III is due to H bonds  $\text{N}-\text{H}\cdots\text{O}-\text{Cl}$ , the partial breaking of which, accompanied by the phase transition III→II, leads to an axial motion of the ions in phase II. A complete breaking of all H bonds in phase I allows the ions to reorient themselves isotropically. The quadrupole coupling constant of rigid  $\text{ClO}_4^-$  ions in this case is  $\sim 1$  MHz.

The temperature dependences of  $^1\text{H}$  NMR absorptions, the  $^1\text{H}$  spin-lattice relaxation time, and the  $^1\text{H}$  spin-spin relaxation time of MAP and its deuterated analog  $\text{CH}_3\text{ND}_3\text{ClO}_4$  were observed in the three solid phases existing over a wide range of temperatures [77]. In phase I, which is stable at temperatures greater than 451 K, the onset of the isotropic reorientation as well as the self-diffusion of the cations have an activation energy of 36 kJ/mol. In phase II, which is stable at 321–451 K, no remarkable change in the motional state of the cation was observed, but a dynamic orientational disorder of  $\text{ClO}_4^-$  anions was expected to occur. In phase III, which is stable below 321 K, the correlated reorientation (defined as the C3 reorientation of the cation having the rigid structure) was observed at lower temperatures, with very small activation energies of only 4.4 and 2.0 kJ/mol.

#### 2.2.2.4 Spectroscopic Properties of Methylammonium Perchlorate

Besides XRD, infrared (IR) spectra of MAP and other amine perchlorates were recorded to clarify structural changes during phase transitions. The IR spectra of amine perchlorates were measured in the solid state and in solution [78]. The appearance of vibrational bands in the solid-state spectra, which are absent in the spectra of the free ion in solution, was interpreted in terms of the lowering of symmetry that occurs when the ion is fixed in the crystal lattice.

The IR spectrum of MAP,  $d. 1.72 \pm 0.005 \text{ g/cm}^3$ , has absorbances at 920, 1067, 1106, 1420, 1460, 2954, 3070, 3127, 3276, and  $3349 \text{ cm}^{-1}$  [72].

A 1978 report on MAP contained details on methods for its preparation and data for solubility, hygroscopicity and IR spectra, thermal stability (DTA, TGA), and sensitivity to impact or friction [69]. This included IR spectra from  $4000$  to  $200 \text{ cm}^{-1}$  of

MAP, deuterated MAP, AP, and deuterated AP, with a list of IR absorption band assignments to fundamental vibrations in the molecule(s). The IR spectra of MAP were compared to those of AP, deuterated MAP, and methylammonium chloride. The MAP absorption band frequencies and assignments were compared to those published by other authors in the literature, and they agreed well with previously published data.

Studies of the temperature variation of the IR and Raman spectra of  $\text{H}_3\text{CNH}_3^+\text{ClO}_4^-$  at 298–460 K showed the presence of two structural phase transitions at 321 and 451 K [79]. The phase III  $\leftrightarrow$  II transition is a reaction of the first order. Phase I exhibits isotropic reorientational motion of the cations and anions.

IR and Raman spectra ( $10\text{--}5000\text{ cm}^{-1}$ ) of  $\text{CH}_3\text{NH}_3\text{ClO}_4$  and  $\text{CH}_3\text{ND}_3\text{ClO}_4$  were investigated at 90–470 K [80]. Assignments of the measured frequencies to the internal modes agreed with those of other investigators. The phase transitions at 321 and 451 K can be characterized based on the temperature dependence of widths and frequencies of prominent bands. In phase III (below 321 K), the cations and anions showed splittings due to non-equivalent sites. In phase II (between 321 and 451 K), the results showed the absence of non-equivalent sites and large motional freedom of the anion. In phase I (above 451 K), the cations and anions underwent isotropic reorientational motions.

#### 2.2.2.5 Solubility of Methylammonium Perchlorate

The solubility of MAP in water at 288 K (15 °C) is 110 g/100 mL and is six times that of AP. MAP was found to be slightly soluble in methyl acetate, 2-butanone (MEK), 1,4-epoxybutane (THF), and 1,4-dioxane. It was only very slightly soluble in ethyl acetate, butyl acetate, and acetic acid [69]. The solubility of MAP in water increased from 110 g/100 g at 263 K (–10 °C) to 250 g/100 g at 303 K (30 °C) [81].

#### 2.2.2.6 Hygroscopicity of Methylammonium Perchlorate

MAP is more hygroscopic than AP but not as hygroscopic as AN. The point of hygroscopicity of MAP varied from 84% relative humidity at 273 K (0 °C) to 59% at 313 K (40 °C) [81]. Minor amounts of  $(\text{CH}_3)_2\text{NH}\cdot\text{HClO}_4$  and  $\text{CH}_3\text{NH}_2\cdot\text{HCl}$  as contaminants in MAP adversely affected the hygroscopic properties of MAP.

When MAP samples were placed in desiccators with constant humidity, there was no mass gain at 55, 66, or 70.4% relative humidity [69]. At 72.6% relative humidity, the sample had gained only 0.02% after 21 d. At 75% relative humidity, MAP is deliquescent. After 16 d it had increased in mass by 28%, and there was a thin layer of liquid in the dish. After 14 d the increase was 53%, and all the MAP was in solution. After 16 d the increase remained constant at 56%. At 88% relative humidity, the uptake of water became even greater: After 2 d, the increase in mass was 27%. The hygroscopic point is at 73% relative humidity.

### 2.2.2.7 Chemical Properties of Methylammonium Perchlorate

Methylammonium perchlorate has a slightly negative oxygen balance of  $-6.1\%$  and qualifies as an energetic material. However, it may be too sensitive to be used in the pure state.

### 2.2.2.8 Thermal Stability of Methylammonium Perchlorate(s)

In DTA, the deflagration temperature of AP is lowered from 768 to  $\sim 583$  K (495 to  $\sim 310^\circ\text{C}$ ) by pressure or by metal catalysts at any pressure. In comparison, the deflagration temperature of MAP or DMAP ( $\sim 573$  K =  $\sim 300^\circ\text{C}$ ) was not significantly lowered by either pressure (Figure 2) or catalysts such as CuO-202. Although the deflagration temperatures of the methylamine perchlorates could not be lowered significantly, their decomposition could be stabilized by the same compounds that stabilize AP (e.g.,  $\text{NaH}_2\text{PO}_4$ ) [82].

**Figure 2:** Differential thermal analysis of methylammonium perchlorate and dimethylammonium perchlorate at 0.1 and 3.44 MPa (1 and 34 atm = 15 and 500 psi, respectively) at a heating rate of  $20^\circ\text{C}/\text{min}$ . (Reproduced and modified from [82].)

The thermal decompositions of the methyl-, dimethyl-, and trimethylammonium perchlorates have been studied over the temperature range 403–593 K ( $130$ – $320^\circ\text{C}$ ) by use of a time-of-flight mass spectrometer [83]. All three methyl-substituted amine salts decompose principally via

in addition to some heterogeneous decomposition. Perchloric acid, formed upon dissociation, appears to undergo limited decomposition to  $\text{ClO}_2$  and  $\text{HCl}$ .

Thermal decomposition of MAP as measured by TGA was initially noted at 533 K (260 °C), with 75% completion in 1 h at 573 K (300 °C) [72]. Holding at higher temperatures led to ignition. The activation energy for the decomposition reactions was 167 kJ/mol (40 kcal/mol). The addition of 5%  $\text{U}_2\text{O}_3$ ,  $\text{MnO}_2$ , or  $\text{Co}_2\text{O}_3$  markedly accelerated the decomposition, whereas  $\text{CuO}$  and  $\text{Fe}_2\text{O}_3$  were less effective.

The effect of particle size and loading density on the rate of decomposition of MAP was measured in comparison to that of AP for loading densities of 0.004–0.1 g/cm<sup>3</sup>, particle sizes 140 and 200 nm, and temperatures of 483–543 K (210–270 °C) [84]. At 493 K, the rate of MAP decomposition increased with decreasing particle size and decreased with increasing loading density. The initial stages of decomposition of MAP and AP were very similar. When heated rapidly, MAP exploded when the temperature reached 611 K (338 °C).

The thermal decomposition of MAP has been studied under isothermal and non-isothermal conditions using DTA [85]. The thermogram showed, in addition to the exotherm due to MAP decomposition, another exotherm at 408 °C, which was observed for the first time but was not confirmed by other investigators. The authors proved that this was due to the decomposition of AP, which had been formed as a decomposition product of MAP. It was suggested that a small fraction of the MAP decomposes via methyl group transfer to form ammonia and methyl perchlorate and that the ammonia then reacts with perchloric acid to form AP. This exotherm was not observed by other authors. Chemical analysis and the IR spectrum of the residue left behind after the decomposition proved it to contain  $\text{NH}_4\text{ClO}_4$ . The results were explained on the basis of a methyl group transfer in addition to proton transfer in the early phases of the decomposition process.

The explosive sensitivity of mono-, di-, and tri- methylammonium perchlorates has been investigated using DTA, TGA, mass spectrometry of pyrolysis products, and explosion delay measurements [86]. The thermal stability of these salts increases with the increase in the number of methyl groups. During thermal decomposition of methylammonium perchlorates, in addition to the proton transfer mechanism, occurrence of methyl group transfer has also been reported. The decomposition temperature of these compounds increased in the order  $\text{CH}_3\text{NH}_3\text{ClO}_4 > (\text{CH}_3)_2\text{NH}_2\text{ClO}_4 > (\text{CH}_3)_3\text{NHClO}_4$ . The activation energy showed the reverse trend, indicating that the stability increases with increasing substitution. Mass spectrometric analysis of decomposition products, however, suggested an increasing reactivity with increasing substitution. It was shown that explosion delay (when dropping samples onto a hot plate or into a heated glass tube) is correlated with thermal stability and impact sensitivity. The DTA trace of tetramethylammonium perchlorate did not show any endotherms or exotherms until the sample started to decompose at 623 K (350 °C).

In the DTA at three different heating rates (5, 10, and 20 °C/min), the first three endotherms showed up at 327, 456, and 534 K (54, 183, and 261 °C) [69]. The transitions are

1. monoclinic to tetragonal
2. tetragonal to cubic
3. melting at 534 K (261 °C)

When a melted sample was heated to 545 K (272 °C) and then allowed to cool, three exotherms appeared at the same temperatures as where the endotherms were observed during heat-up. The phase-change process is thus reversible. The DTA exotherm was between 609 and 612 K (336 and 339 °C), and that one is NOT reversible.

Comparing the thermal stability and strand-burning rates of the four methylammonium perchlorates with increasing numbers of methyl substituents to the properties of AP, it was concluded that a critical point was reached when the temperature of the crystal provided sufficient energy to allow free rotation of the  $\text{ClO}_4^-$  ions. For MAP, this temperature is 453 K (180 °C), compared with 513 K (240 °C) for AP. This free rotation (and phase change) leads to a reactivity that is reflected in lower DTA exotherms. Table 5, presented earlier, contains a summary of thermal stability data and other physical properties of several methyl-substituted amine nitrates.

A cold matrix isolation–IR spectroscopic technique showed that MAP vaporizes by dissociation: [87, 88]

The relative vaporization temperatures of ammonium and alkylammonium salts can be correlated with the  $\text{pK}_a$  values of the bases in aqueous solution.

#### 2.2.2.9 Strand-Burning Rates of Methylammonium Perchlorate

Methylammonium perchlorate is a close relative of AP, differing from the latter only in the presence of a methyl group where a hydrogen atom used to be. The unusual difference between the two energetic salts is that the strand-burning rate of MAP is an order of magnitude higher than that of AP.

Pressed strands of MAP burn approximately ten times as fast as AP at 2.06 MPa (300 psi) and have a pressure exponent of approximately 1. The burning rate of MAP pellets pressed in a die at 82 MPa (12000 psi) is shown in Figure 3.

In another series of strand-burning tests with methylammonium perchlorates, where –40+50 mesh oxidizer powder was loaded into paper straws 6 mm in diameter at low bulk densities (40–50% that of the solid crystal), the burning rate of MAP was 2.5 times that of AP, while tetramethylammonium nitrate burned only half as fast as AP (Table 27) [70, 71, 89].

The strand-burning rate of MAP at 100–500 MPa was 10 times that of AP [90]. The range of pressures where stable combustion is obtained differed quite a bit, also. This phenomenon needed an explanation, and this is why burning rates of pressed MAP pellets have been extensively investigated, but the early results were sometimes quite contradictory. There was hope that MAP additions to AP might improve its burning behavior, both as a strand-burning oxidizer by itself and in propellant formulations.

**Figure 3:** Burning rate of pressed pellets of methylammonium perchlorate. (Reproduced and modified from [82].)

**Table 27:** Strand-burning rates of methylammonium perchlorates.

| Compound                      | Burning rate, cm/s | Bulk density, % of solid crystal density |
|-------------------------------|--------------------|------------------------------------------|
| Methylammonium perchlorate    | 0.103 ± 0.005      | 50                                       |
| Dimethylammonium perchlorate  | 0.132 ± 0.004      | 43                                       |
| Trimethylammonium perchlorate | 0.065 ± 0.013      | 45                                       |
| Trimethylammonium perchlorate | 0.111 ± 0.006      | 31                                       |
| Tetramethylammonium nitrate   | 0.022 ± 0.005      | 40                                       |
| For comparison:               |                    |                                          |
| Ammonium perchlorate          | 0.043 ± 0.002      | 51                                       |

Note: Burning rates at 101 kPa in paper straws 6 mm in diameter

Data source: [70,71]

MAP burning was stable starting at 2 atm, burning at a rate of 2.1 mm/s. In the intermediate range from 11 to 60 atm, the combustion was unstable and could not be sustained. At much higher pressures (up to 300 atm), the combustion stabilized again. Another study attempted to predict the burning rate based on a theory of similarity; the predicted burning rate at atmospheric pressure (if you could get it to burn at such a low pressure; the strand would probably need to be prewarmed or confined) would be 1.44 mm/s.

The burning rates of MAP were measured using strands of MAP powder pressed into Plexiglas tubes with diameters of 4, 5, 7, or 10 mm. The dependence of strand-burning rate on the initial strand temperature was tested from 293 to 443 K (20 to 170 °C) in the pressure regime from 1 to 40 atm [91]. The temperature coefficient was  $0.0044 \text{ K}^{-1}$ , and it decreased with increasing temperature. The burning rate of MAP is already higher than that of AP, and it may not be necessary to add a burning-rate catalyst. Nevertheless, a range of catalysts, typically added in the amount of 2%, was tested in the hope of allowing MAP to burn reproducibly over a wider pressure range. The effectiveness of catalysts decreased in the order  $\text{CuCr}_2\text{O}_4 > \text{V}_2\text{O}_5 > \text{Fe}_2\text{O}_3 > \text{SiO}_2$ . The addition of 3%  $\text{NH}_4\text{Cl}$  had a strong inhibiting effect.

In another effort to explain the difference in burning rates of MAP and AP, the burning surface temperature was measured using embedded capillary (10  $\mu\text{m}$ ) thermocouples (W5Re/W20Re). This allowed the measurement of the temperature profile in the combustion wave as it progressed through the strand (and eventually consumed the thermocouple) [92]. The salts were pressed into cartridges (7-mm inner-diameter [ID] Plexiglass tubes, bulk density  $d = 0.97 - 0.98 \text{ g/cm}^3$ ) and were burned in nitrogen in a constant pressure bomb at 1–54 atm. The temperature distribution in the condensed phase of the burning cartridges increased smoothly from room temperature to  $\sim 523 \text{ K}$  ( $\sim 250^\circ\text{C}$ ). The maximum combustion temperature was dependent on the pressure: At 1 atm the maximum temperature was 2253 K ( $1980^\circ\text{C}$ ), at 18 atm it was 2773 K ( $2500^\circ\text{C}$ ), and at 54 atm it was 2813 K ( $2540^\circ\text{C}$ ).

#### 2.2.2.10 Safety Properties of Methylammonium Perchlorate

The drop-weight impact sensitivity of AP, RDX, and MAP was measured on a U.S. Bureau of Mines (USBM) machine with 2-kg mass. The 50% fire point was 100, 33, and 20 cm, respectively. MAP is the most sensitive of the three explosives. For comparison, the drop-weight impact sensitivity of di-, tri-, and tetramethylammonium perchlorate is 22, 25, and 35 cm, respectively [33].

An accidental explosion occurred when MAP crystals that had settled from a saturated solution and were still covered by supernatant liquid were stirred with a rod [93].

Table 28 gives a comparison of the drop-weight sensitivities of several methylammonium perchlorates with increasing number of methyl groups in the molecule. The 50% fire point data were obtained on a USBM apparatus and were previously reported by Stammeler in an unidentified Aerojet report.

In a U-tube adiabatic compression sensitivity test apparatus with variable, pre-selected push pressure and constant bubble size, aqueous solutions containing 65% MAP or 70% ethylenediammonium(2+) diperchlorate could not be made to explode at the maximum energy input capability of the apparatus; this was much less sensitive than glycerol trinitrate or ethylene glycol dinitrate (EGDN) [94].

**Table 28:** Drop-weight impact sensitivities of methylammonium perchlorates.

| Compound name                   | Drop-weight impact sensitivities |            |                   |                         |               |                   |
|---------------------------------|----------------------------------|------------|-------------------|-------------------------|---------------|-------------------|
|                                 | in-lb                            |            |                   | m-kg                    |               |                   |
|                                 | No fire in<br>10 trials          | First fire | 50% fire<br>point | No fire in<br>10 trials | First<br>fire | 50% fire<br>point |
| Methylammonium perchlorate      | 18                               | 22         | 35                | 20.7                    | 25.3          | 40.3              |
| Dimethylammonium perchlorate    | 28                               | 32         | 38                | 32.2                    | 36.8          | 43.7              |
| Trimethylammonium perchlorate   | 32                               | 36         | 43                | 36.8                    | 41.4          | 49.5              |
| Tetramethylammonium perchlorate | —                                | —          | 61                | —                       | —             | 70.2              |
| For comparison:                 |                                  |            |                   |                         |               |                   |

Data source: [70]

**2.2.2.11 Explosive Performance Properties of Methylammonium Perchlorate**

The Trauzl lead block indentation caused by MAP is 160% that of trinitrotoluene (TNT), or 470 cm<sup>3</sup>. The detonation velocity is 7540 m/s at 1.68 g/cm<sup>3</sup>, compared to 7665 m/s for tetryl under the same conditions. The detonation velocity is 6600 m/s at a lower packing density of 1.565 g/cm<sup>3</sup>.

The detonability of aqueous solutions of organic amine perchlorates was studied in steel and glass ampoules with an electric or intermediate hexogen detonator. The detonation temperature of aqueous solutions of MAP was 1740–1880 K, and the concentration limit of H<sub>2</sub>O below which the solutions retained their detonation capacity was 39%–42% H<sub>2</sub>O [95].

**2.2.2.12 Applications of Methylammonium Perchlorate**

There are many patents claiming the use of MAP in explosive formulations, either by itself or in combination with other explosives.

Because the material is so sensitive, it would be difficult to use it as a rocket propellant. Nevertheless, there are some patented propellant formulations in which MAP is supposed to give a performance advantage over other oxidizers [96].

### 2.2.3 Other Methylammonium Salts

Methylammonium dinitramide,  $[\text{H}_3\text{CNH}_3^+][\text{N}(\text{NO}_2)_2]^-$ , melts at 316–318 K (43–45 °C) [97]. The enthalpy of formation was measured as  $-121 \text{ kJ/mol}$  ( $-28.9 \text{ kcal/mol}$ ) [98]. The density of pressed methylammonium dinitramide pellets was  $1.53 \text{ g/cm}^3$ .

Methylammonium nitroformate, dimethylammonium nitroformate, and ethylenediammonium dinitroformate were prepared, and the crystal structures were examined by XRD, NMR, and Raman and IR spectroscopy, and the enthalpies of formation were predicted by computational chemistry [99]. All the nitroformate salts had higher predicted detonation pressures and velocities than TNT.

### 2.2.4 Dimethylammonium Salts

Dimethylamine is a stronger base than ammonia and forms salts with a wide range of acids. Salts of dimethylamine with oxidizing acids have explosive power and are potential propellant ingredients.

#### 2.2.4.1 Dimethylammonium Nitrate

Dimethylammonium nitrate,  $(\text{H}_3\text{C})_2\text{NHNO}_3$ , CAS RN [30781-73-8], is thermally more stable than the monomethylammonium nitrate. There are no known applications of this chemical as a rocket propellant.

#### 2.2.4.2 Physical Properties of Dimethylammonium Nitrate

The physical properties of dimethylammonium nitrate are summarized in Table 5. Dimethylammonium nitrate crystals are composed of discrete cations and anions that are connected by classical  $\text{N}-\text{H}\cdots\text{O}$  bonds. Geometric parameters are in the usual ranges [100].

#### 2.2.4.3 Thermal Stability of Dimethylammonium Nitrate

The thermal decomposition of mono-, di-, and trimethyl-ammonium nitrates has been examined using DTA, TGA, and MS methods [56]. The decomposition temperature of these compounds decreased in the sequence  $\text{CH}_3\text{NH}_3\text{NO}_3 > (\text{CH}_3)_2\text{NH}_2\text{NO}_3 > (\text{CH}_3)_3\text{NHNO}_3$ . The activation energies have been determined by employing an isothermal decomposition technique. Mass spectrometric investigation showed that the rate of decomposition increased with increasing substitution on the nitrogen atom.

#### 2.2.4.4 Dimethylammonium Perchlorate

Dimethylammonium perchlorate,  $(\text{H}_3\text{C})_2\text{NHClO}_4$ , CAS RN [14488-49-4], is thermally more stable than the monomethylammonium perchlorate. There are no known applications of this chemical as a rocket propellant.

### 2.2.4.5 Physical Properties of Dimethylammonium Perchlorate

Differential scanning calorimetric data revealed the existence of three different phase modifications in dimethylammonium perchlorate, analogous to those observed in mono- and trimethylammonium perchlorate. An analysis of the NMR data, the temperature dependence of proton and deuteron line shapes, and spin-lattice relaxation times reported for  $(\text{CH}_3)_2\text{NH}_2\text{ClO}_4$  and its selectively deuterated analog  $(\text{CH}_3)_2\text{ND}_2\text{ClO}_4$  enabled identification of the molecular motions occurring in the respective phases and determination of their activation parameters [101]. In the low-temperature phase III, which is stable below 309 K, there are two non-equivalent dimethylammonium cations that manifest themselves by different reorientation frequencies of methyl groups about their threefold symmetry axes  $C_3$  and by reorientation of one of the two inequivalent cations about its pseudo-threefold symmetry axis  $C'_3$  lying along one of the two N—D bonds. The intermediate phase II had not been reported previously. It was found to be stable in the temperature range 309–311 K, but it can easily be undercooled below 290 K. There is a large entropy change of  $25.5 \text{ J mol}^{-1} \text{ K}^{-1}$  associated with the III→II transition, which indicates that the  $\text{ClO}_4^-$  ions in phase II have considerable motional freedom, presumably due to breaking of N—H...O hydrogen bonds.

A temperature-dependent study of the widths and frequencies of prominent Raman and IR spectra ( $20\text{--}5000 \text{ cm}^{-1}$ ) of  $(\text{CH}_3)_2\text{NH}_2\text{ClO}_4$  and its N-deuterated analog at 90–350 K confirmed the existence of phase transitions at 309 and 311 K [102]. In the high-temperature phases II and I, the cations and anions undergo reorientational motions.

Table 11 (presented previously) contains a summary of the physical properties of dimethylammonium perchlorate.

### 2.2.5 Trimethylammonium Salts

#### 2.2.5.1 Trimethylammonium Nitrate

Trimethylammonium nitrate, CAS RN [25238-43-1], shows two solid-state phase transformations, one at 359 K (86 °C) and one at 409 K (136 °C). The liquid gun propellant LP1776 is (was) a solution of 60% HAN and 20% trimethylammonium nitrate in water.

**Table 29:** Thermodynamic properties of trimethylammonium nitrate.

| Compound name             | Gross formula                                 | Enthalpy of formation |          |       |       | References    |
|---------------------------|-----------------------------------------------|-----------------------|----------|-------|-------|---------------|
|                           |                                               | kJ/mol                | kcal/mol | J/g   | cal/g |               |
| Trimethylammonium nitrate | $\text{C}_3\text{H}_{10}\text{N}_2\text{O}_3$ | –305.7                | –73      | –2503 | –598  | [103], p. 380 |
|                           |                                               | –343.8                | –82.2    | –2815 | –673  | [15], p. 345  |
|                           |                                               | –346.4                | –82.8    | –2837 | –678  | [27]          |

$$M = 122.12 \text{ g/mol} = 8.189 \text{ mol/kg}$$

There is quite a discrepancy in the enthalpies of formation reported for trimethylammonium nitrate in the third and sixth editions of the Meyer-Koehler-Homburg text *Explosives* (Table 29). It is assumed that the more recent value is the more reliable one.

### 2.2.5.2 Trimethylammonium Perchlorate

Trimethylammonium perchlorate, CAS RN [15576-35-9], has been tested as an additive to AP, and the burning rates of compressed pellets of AP and trimethylammonium perchlorate were measured in a strand burner [104]. A mixture containing 80% trimethylammonium perchlorate had the highest burning rate. Table 11 contains a summary of the physical properties of trimethylammonium perchlorate.

### 2.2.5.3 Trimethylammonium Dinitramide

Trimethylammonium dinitramide,  $[\text{HN}^+(\text{CH}_3)_3][\text{N}^-(\text{NO}_2)_2]$ ,  $\text{C}_3\text{H}_{10}\text{N}_4\text{O}_4$ , CAS RN [165603-94-1], is an energetic salt with a low melting point.

## 2.2.6 Quaternary Tetramethylammonium Salts

There are several tetramethylammonium salts with oxidizing anions that are of interest as fuels for  $\text{HNO}_3$ -based monopropellants or as additives to trimethylamine as a fuel. This includes nitrates, perchlorates, azides, and the fluorohalogenates [105].

### 2.2.6.1 Tetramethylammonium Nitrate

Tetramethylammonium nitrate,  $\text{C}_4\text{H}_{12}\text{N}_2\text{O}_3$ , TeMAN, CAS RN [1941-24-8], is the quaternary salt of trimethylamine and can be prepared by metathetical reaction of tetramethylammonium bromide (or iodide) with silver nitrate. Quaternary alkylammonium salts are relatively stable to further oxidation. Therefore, some monopropellants have been formulated by dissolving quaternary ammonium salts in concentrated nitric acid (CAVEA; see *Encyclopedia of Monopropellants*, chapter “Nitric Acid or Perchloric Acid-Based Monopropellants”). The physical properties of tetramethylammonium nitrate are summarized in Table 30.

**Table 30:** Physical properties of tetramethylammonium nitrate.

| Property                                 | SI units               |               | Other units    |              | References   |
|------------------------------------------|------------------------|---------------|----------------|--------------|--------------|
| Molecular mass                           | 136.15 g/mol           | 7.345 mol/kg  | —              | —            |              |
| Density at 293 K                         | 1.30 g/cm <sup>3</sup> | —             | —              | —            | [106]        |
| Enthalpy of formation $\Delta H_f^{298}$ | −341.5 kJ/mol          | −2507.3 kJ/kg | −81.6 kcal/mol | −599.3 cal/g | [15], p. 305 |
|                                          | −331.8                 | −2437 kJ/kg   | −79.3 kcal/mol | −582.5 cal/g | [16]         |
|                                          | ± 0.1 kJ/mol           |               |                |              |              |
|                                          | −355.5 kJ/mol          | −2611 kJ/kg   | −85.0 kcal/mol | −624 cal/g   | [27]         |

The standard enthalpy of formation of crystalline tetramethylammonium nitrate is  $-331.8 \pm 0.1$  kJ/mol [16]. That of the corresponding crystalline tetramethylammonium azide is  $+150.1 \pm 1.0$  kJ/mol.

The mechanism of thermal decomposition of tetramethylammonium nitrate was studied using TGA and MS [107]. The first step of the decomposition is the dissociation of the salt into trimethylamine and methyl nitrate. The activation energy was 368 kJ/mol (88 kcal/mol), which is close to the dissociation energy of a N—CH<sub>3</sub> bond. The rate-determining step in the dissociation process appears to be the transfer of a methyl group. In air, at atmospheric pressure the DTA of TeMAN showed an overall exotherm at 373 °C, indicating the predominance of decomposition rather than dissociation (sublimation step). The kinetics of thermal decomposition in solid state in air was studied by several methods. The measured activation energies varied between 343 and 368 kJ/mol (82 kcal/mol and 88 kcal/mol) depending on the method used.

A high-pressure FTIR study of tetramethylammonium nitrate at up to 50 kbar using a diamond anvil cell in the frequency region 4000–400 cm<sup>-1</sup> showed that in the high-pressure phase above 30 kbar, both cation and anion bands underwent drastic changes in position, band width, and intensity [108]. Pressure-induced phase transitions were caused by the distortion of the cations and anions with increased disorder and symmetry variations.

Tetramethylammonium nitrate is not as detonable as the lower members of this series of alkylammonium salts. After three recrystallizations from water, the melting point of tetramethyl ammonium nitrate (TMA) was 683 K (410 °C), and the crystal density was 1.25 g/cm<sup>3</sup>. After the powder was compressed at 3400 kg<sub>f</sub>/cm<sup>2</sup>, the pellet density was 1.22 g/cm<sup>3</sup>. Pure TMA had essentially no explosive properties [106]. It is thermally stable and cannot be detonated by impact or by initiation with a pentaerithritol tetranitrate (PETN) booster. TMA is less hygroscopic than AN, although mixtures with AN are more hygroscopic. A eutectic consisting of 25% TMA and 75% AN melted at 411 K (138 °C). The zero-oxygen balance mixture (13.4% TMA+86.6% NH<sub>4</sub>NO<sub>3</sub>) could be detonated with 1.5 g Hg fulminate as the initiator, while the eutectic required 2.0 g. Compressing powder of the zero-balance mixture gave the following pellet properties: pressure (kg<sub>f</sub>/cm<sup>2</sup>), density (g/cm<sup>3</sup>) 170, 1.35; 340, 1.49; 680, 1.58; 3400, 1.60. The detonation velocity (m/s) as a function of density (g/cm<sup>3</sup>) was 3130, 0.90; 3020, 1.0; failure at 1.1. In the lead block test, this mixture caused an indentation 112% of the power of picric acid. It was detonated by impact with a 10-kg weight falling 3 m in 20% of the trials.

### 2.2.6.2 Tetramethylammonium Perchlorate

Tetramethylammonium perchlorate, C<sub>4</sub>H<sub>12</sub>N<sub>1</sub>ClO<sub>4</sub>, TeMAP, CAS RN [2537-36-2], is the quaternary salt of trimethylamine and can be prepared by metathetical reaction of tetramethylammonium bromide (or iodide) with silver perchlorate. Quaternary alkylammonium salts are relatively stable to further oxidation. The effect of TeMAP on the thermal decomposition and strand-burning rate of AP has been investigated and was

found to be quite different from the effect of MAP or DMAP. TeMAP deflagrates in DTA between 653 and 683 K (380 and 410 °C), and this temperature is not significantly affected by pressure, catalysts, or basic additives [82]. The data suggest the possibility of a direct exothermic oxidation of the substituted ammonium ion by the perchlorate ion.

Co-crystallizing AP with TeMAP will enhance the burning rate of composite solid propellants made with the modified AP/TeMAP oxidizer [109, 110].

The decomposition of TeMAN and TeMAP in the presence of small amounts of chromium(VI) trioxide was analyzed using DTA and TGA, and it was revealed that  $\text{CrO}_3$  does have a sensitizing effect on the thermal decomposition of these salts [111].

Table 30 (presented previously) contains a summary of physical properties of TeMAP. Crystals of TeMAP are tetragonal with  $a = 8.343 \pm 0.002 \text{ \AA}$  and  $c = 5.982 \text{ \AA}$  [112]. The space group is  $P4/nmm$  with  $Z = 2$ . The  $(\text{CH}_3)_4\text{N}^+$  ions conform very closely to the symmetry of a regular tetrahedron, with  $r \text{ C-N} = 1.470 \pm 0.014 \text{ \AA}$  and  $\angle \text{C-N-C}$  angles of 109.4 and 109.5°.

In the room-temperature phase of TeMAP, the  $\text{ClO}_4^-$  ions are disordered, with four possible equivalent orientations. There is an order-disorder transition at 170 K, revealed by heat capacity and low-temperature XRD structure determinations [113]. *Ab initio* calculations of the electrostatic intermolecular interaction suggested an almost two-dimensional (2D) system. Monte Carlo simulations for 2D and three-dimensional (3D) interaction schemes showed that the 3D scheme agreed better with the experimental data.

Single-crystal XRD structure determinations of the low-temperature crystal structures of TeMAP at 210 K gave space group  $P4/nmm$ , with  $a_1 = 8.2376(14)$ ,  $c_1 = 5.8256(12) \text{ \AA}$ , and  $Z = 2$  [114]. Below  $T_c = 170 \text{ K}$ , these groups ordered in four sublattices, with each ion gradually choosing one unique orientation. The low-temperature modification crystallized in the orthorhombic space group  $P2_12_12$ , with  $a_3 = 11.714(3) \text{ \AA}$ ,  $b_3 = 11.784(3) \text{ \AA}$ ,  $c_3 = 5.8265(9) \text{ \AA}$ , and  $Z = 4$ . The structural models and the phase transitions were explained from electrostatic octopole-octopole interactions among the  $\text{ClO}_4^-$  groups within layers perpendicular to the c-axis.

### 2.2.6.3 Tetramethylammonium Azide

Tetramethylammonium azide,  $\text{N}(\text{CH}_3)_4 \text{N}_3$ , can be dissolved in trimethylamine to improve the performance of this amine as a rocket fuel and to make it easier to handle by lowering its vapor pressure. It is also used in the synthesis of other energetic azides. It can be prepared by reaction of trimethylsilylazide with tetramethylammonium fluoride in acetonitrile [115, 116]:

$\text{CH}_3\text{CN}$  as the solvent

Earlier methods for preparation of  $\text{N}(\text{CH}_3)_4 \text{N}_3$  required the use of shock-sensitive starting materials, i.e.,  $\text{AgN}_3$  or  $\text{HN}_3$ . The new method allows preparation of azides with high purity, at room temperature, and without the use of shock-sensitive materials.

The standard enthalpy of formation of crystalline tetramethylammonium azide is  $+150.1 \pm 1.0 \text{ kJ/mol}$  [16]. The positive enthalpy of formation should make it a good propellant additive.

#### 2.2.6.4 Tetramethylammonium Dinitramide

The enthalpy of formation of tetramethylammonium dinitramide,  $[\text{N}(\text{CH}_3)_4][\text{N}(\text{NO}_2)_2]$ , CAS RN [140456-75-3], is  $-103.3 \pm 1.1 \text{ kJ/mol}$  ( $-24.7 \pm 0.26 \text{ kcal/mol}$ ) [117]. Other sources reported an enthalpy of formation for tetramethylammonium dinitramide of  $-191 \text{ kJ/mol}$  ( $-45.6 \text{ kcal/mol}$ ) [98]. Tetramethylammonium dinitramide melts at  $507\text{--}511 \text{ K}$  ( $234\text{--}238^\circ\text{C}$ ) [97]. The density of a pressed pellet of tetramethylammonium dinitramide is  $1.22 \text{ g/cm}^3$ .

#### 2.2.6.5 Tetramethylammonium Halogenides and Halogenates

The tetramethylammonium cation is stable enough to survive reaction with trifluorobromates and trifluoroiodates, forming stable salts that are nevertheless very energetic and potentially explosive [105].

### 3 Ethylamines

There are three ethylamines, and all three are potentially useful as rocket propellants, more so than the corresponding methylamines:

|                                              |                                     |                   |
|----------------------------------------------|-------------------------------------|-------------------|
| Ethylamine (sometimes called monoethylamine) | $\text{C}_2\text{H}_5\text{NH}_2$   | CAS RN [75-04-7]  |
| Diethylamine                                 | $(\text{C}_2\text{H}_5)_2\text{NH}$ | CAS RN [109-89-7] |
| Triethylamine                                | $(\text{C}_2\text{H}_5)_3\text{N}$  | CAS RN [121-44-8] |

In addition, substitution at the ends of the ethyl group in ethylamine molecules by amino groups, hydroxyl groups, hydrazido groups, cyano groups, or azido groups will improve the water solubility; lower the freezing point; and, in the case of hydrazido, cyano, and azido groups, improve the rocket performance of ethylamines as fuels. Several such substituted ethylamines are described in later sections of this book.

#### 3.1 Production of Ethylamines

The production of ethylamines by reaction of ethanol or ethylene with ammonia under pressure results in a mixture of the primary, secondary, and tertiary ethylamines, which must be separated by fractionated distillation in a distillation column. Because mono- and triethylamine do not have the same market demand as diethylamine, they

are sometimes recycled into the reaction chamber. Diethylamine can thus be obtained in 90% yield.

### 3.2 Physical Properties of Ethylamines

Ethylamine (monoethylamine) boils just below room temperature, so it can be stored as a liquid at room temperature under slight overpressure or in a refrigerator. The other two ethylamines are liquids at room temperature. The physical properties of ethylamines are summarized in Table 31.

**Table 31:** Physical properties of ethylamines.

| Property                               | Unit                   | Ethylamine<br>$\text{C}_2\text{H}_5\text{NH}_2$ | Diethylamine<br>$(\text{C}_2\text{H}_5)_2\text{NH}$ | Triethylamine<br>$(\text{C}_2\text{H}_5)_3\text{N}$ |
|----------------------------------------|------------------------|-------------------------------------------------|-----------------------------------------------------|-----------------------------------------------------|
| Freezing point                         | K                      | 192                                             | 223                                                 | 158.3                                               |
|                                        | °C                     | −81.0                                           | −50                                                 | −114.8                                              |

Data source: [118]

The vapor pressure of ethylamine can be calculated from the Antoine equation

$$\ln p_{\text{sat}} = A - B/(T + C)$$

where  $p_{\text{sat}}$  is the saturation pressure in kPa,  $T$  is the temperature in kelvin,  $A = 6.1203$ ,  $B = 964.494$ , and  $C = -55.34$  for the pressure range 20–200 kPa.

Of all the amines in this chapter, triethylamine is the one most frequently used as rocket fuel. For this reason, we have assembled additional data on its physical properties in Table 32. These properties listed in Table 32 may or may not match the older data listed in Table 31.

**Table 32:** Physical properties of triethylamine.

Both PEPCODED.DAT [27] and NIST [29] display a disparity in three sets of data from the literature for the enthalpy of formation of liquid triethylamine that has not yet been resolved.

The heat of vaporization of triethylamine in the range of 298 to 352 K can be calculated from the equation

$$\Delta H_{\text{vap}} = 50.32 \exp(0.2684 \times T_r)(1 - T_r)^{0.2684}$$

where  $\Delta H_{\text{vap}}$  is the heat of vaporization in kJ/mol and  $T_r$  is the reduced temperature, which is the quotient of the temperature (in kelvin) and the critical temperature, which is 535.6 K.

The vapor pressure of triethylamine in the range of 323 to 367 K can be calculated from the equation

$$\log 10(P) = 2.98368 - [695.814/(T - 128.271)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

### 3.3 Chemical Properties of Ethylamines

Ethylamines are thermally stable and react hypergolically with most types of nitric acid. The ethylamine most frequently used as rocket fuel is triethylamine. Ethylamines would auto-oxidize slowly. The main concern during exposure of any amine to air is the uptake of carbon dioxide. Some (less volatile) amines are used in the chemical and natural gas industry for removal of carbon dioxide and hydrogen sulfide from sour gas process streams.

For occasional instant spot checks of triethylamine vapor concentration in the air at the workplace, the easiest method is with gas-detection tubes that contain an indicator supported on a granular material that changes color when exposed to ammonia. Such tubes are available from Draeger, MSA, Kitagawa, and other suppliers. Gas-detection tubes are sensitive to as little as 5 ppm  $(\text{C}_2\text{H}_5)_3\text{N}$  and can measure up to 60 ppm  $(\text{C}_2\text{H}_5)_3\text{N}$  with ten strokes [122].

### 3.4 Handling of Ethylamines

Due to their lower vapor pressure, ethylamines are easier to handle than methylamines. Protective clothing to be worn when handling ethylamines under pressure includes gloves, goggles, and aprons. Ethylamines must be handled as flammable liquids. The lower flammable limit of ethylamine in air is 3.5 vol-%, and the auto-ignition temperature is 658 K (385 °C). The flammable range of diethylamine in air is 1.8–10 vol-%. The flammable range of triethylamine is 1.2–8 vol-%. One must avoid spills and remove any potential sources of ignition.

### 3.5 Toxic Properties of Ethylamines

The fishy odor of ethylamines is very similar to that of methylamines, and may be even a little fishier than those. The obnoxious odor is sufficient warning to stay away from ethylamine(s) vapors.

As of 2005, the National Institute for Occupational Safety and Health (NIOSH) recommended exposure limit (REL) time-weighted average (TWA) for diethylamine was 10 ppm (30 mg/m<sup>3</sup>), with a short-term excursion allowance of 25 ppm (75 mg/m<sup>3</sup>), and the U.S. Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) TWA was also 25 ppm (75 mg/m<sup>3</sup>). The original NIOSH immediately dangerous to life or health (IDLH) limit for diethylamine was 2000 ppm, but it was lowered by one order of magnitude to 200 ppm because of safety considerations a few years later. The threshold limit value (TLV) TWA for triethylamine is 1 ppm, and the short-term exposure limit (STEL; ceiling) is 3 ppm.

As of 2005, no REL had been established for triethylamine. The 1994 OSHA PEL TWA for triethylamine was 25 ppm (100 mg/m<sup>3</sup>), which was an increase from the 1989 value of 10 ppm. The 1993–1994 American Conference of Governmental Industrial Hygienists (ACGIH) TLV TWA was 5 ppm (12 mg/m<sup>3</sup>), and it was 15 ppm (36 mg/m<sup>3</sup>) for a short-term excursion STEL. The original NIOSH (Standard Completion Program) IDLH was 1000 ppm, but that was lowered to 200 ppm based on acute inhalation toxicity data in animals. The chosen IDLH was based on a report that a 4-h exposure to 1000 ppm triethylamine killed one of six rats.

### 3.6 Propellant Mixtures with Ethylamines

A hypergolic fuel mixture consisting of 50 mass-% triethylamine and 50 mass-% xylylidine with the code name of Tonka 250 was used in Germany during World War II in missiles developed by BMW; it had the code name TX-1 used by SEPR in France and was later used under the code name Samin (Samine) for several different missiles in Russia (USSR) [123]. At the end of the Cold War, large quantities of this material had to be demilitarized in compliance with the Strategic Arms Limitation Talks (SALT) disarmament agreements [124]. Unfortunately, the storage conditions were not carefully controlled, and some of the mixture had already leaked into the ground. The abandoned storage magazines constituted a hazard to the surrounding communities [125]. Various weapon systems were using the Samin fuel blend and had to be demilitarized [126].

At one time, 290 metric tons of Samin (TG-02) were stored at the Mingachevir depot in Azerbaijan, waiting for disposal. Color pictures of the unsafe conditions at the neglected storage sites are shown on page 19 of the Winkelmann thesis [127]. Where the fuel had leaked into the ground, it had formed a reddish-brown layer of xylylidine auto-

oxidation products that was sometimes revealed only if the sand drifts were scraped and moved to the side.

Several different methods were evaluated for not only disposing of but also converting the abandoned and unwanted rocket propellants, including Samin and Melanj, into commercially useful products, such as fertilizer or plastics [128–131].

The storage stability of Samin depends significantly on fuel oxidation with the air trapped in the storage tanks. Intuitively, one would guess that xylidine is more susceptible to auto-oxidation than triethylamine. Thus, it is unclear why a reduction of the triethylamine concentration (and not the xylidine concentration) from 50.2 mass-% to less than 48% was defined as the end of shelf life of the propellant. After experimental data were obtained from accelerated storage stability tests, the shelf life of Samin was estimated using the Arrhenius equation [132]. According to the kinetic studies, the oxidation reaction of the amine was a zero-order reaction, and the shelf lives of Samin in stainless-steel tanks at 293, 298, and 303 K (20, 25, and 30 °C) were 5.7, 3.7, and 2.4 years, respectively. Use of an inert gas such as nitrogen would extend the storage life. Similar results were obtained with the Berthelot equation [133].

### 3.7 Ethylammonium Salts

#### 3.7.1 Mono-, Di-, and Triethylammonium Nitrates

Ethylammonium nitrate, 1-ethylammonium nitrate; ethanamine, nitrate (1:1);  $\text{H}_3\text{C}-\text{CH}_2-\text{NH}_3^+\text{NO}_3^-$ , CAS RN [22113-86-6]; EAN, has found only a few applications in rocket propellants. At one time it was considered as a fuel in HAN-based mono-propellants. A significant property of ethylammonium nitrate is its very low melting point, at below room temperature (287 K = 14 °C). Ethylammonium nitrate is the simplest organic ionic liquid.

Eutectics of EAN with MEAN or *n*-propylammonium nitrate lower the melting point even further. Such ionic liquids have been evaluated not only as propellant ingredients but also as electrolytes in batteries, fuel cells, and other electrochemical applications.

#### 3.7.2 Physical Properties of Mono-, Di-, and Triethylammonium Nitrates

Physical properties of ethylammonium nitrate are summarized in Table 33.

Ethylammonium nitrate is not only an ionic liquid, but it is also a room-temperature ionic liquid with an unusually low melting point. It owes its unique physical properties and molecular structure to a three-dimensional hydrogen-bonded network, similar to water. EAN was the first ionic liquid recognized by a rocket propellant chemist for its potential use as a rocket propellant.

In his memoir surveying this lifetime work, John D. Clark makes mention of ionic liquids in general and EAN in particular: “*Molten salts are nothing new, but these were*

**Table 33:** Physical properties of ethylammonium nitrate.

*the only ones I ever heard of that were liquid at 25 °C. I've never found a use for the ethylamine compound, but something with such interesting properties ought to be good for something!"* [38], p. 140. John was correct in this prediction.

Ethylammonium nitrate has been proposed as a non-aqueous solvent for a wide variety of chemical reactions where water would interfere. Water was used as a co-solvent to study the molecular structure of EAN melts [134]. Densities, partial molar volumes, and heat capacities of EAN solutions with 0.4–99.9 mass-% EAN were measured between 288 and 318 K (15 and 45 °C). The partial molar volume of EAN increases between mole fractions of  $X_2 = 0.02$  and 0.4 and remains constant above 0.4. The partial molar heat capacity of EAN has a sharp sigmoid increase up to  $X_2 = 0.075$  and remains constant for all mole fractions above 0.1. The viscosity of EAN at 298 K is about 24 times that of water. In EAN/water mixtures, the viscosity rises sharply above EAN mole fractions of 0.8.

Multiple crystal pathways and crystal polymorphs were observed in protic ionic liquids (pILs), which are liquids at room temperature [135]. The pILs investigated were MEAN, dimethylammonium nitrate, EAN, and *n*-propylammonium nitrate. Methylammonium nitrate and dimethylammonium nitrate solidified as plastic crystals at room temperature, whereas EAN and *n*-propylammonium nitrate were liquids at room temperature. Despite its simple molecular structure, complicated phase behaviors such as multiple crystal pathways and crystal polymorphs were observed in liquid EAN at low temperature. Liquid *n*-propylammonium nitrate also exhibited low-temperature anomalies similar to those observed with liquid EAN. Rapid proton exchanges, which disturb the crystal nucleation of liquid pILs at room temperature, cause multiple crystal rearrangement pathways via non-equilibrium states.

An ionic liquid metalized fuel consisting of 61.6% EAN, 23% nano-boron, 11.55% H<sub>2</sub>O, and 3.85% AN was evaluated as a fuel with a hydrogen peroxide solution as the oxidizer, and the strand-burning rates of the fuel components by themselves were determined in a windowed constant pressure bomb [136]. The freezing point of the EAN/B/H<sub>2</sub>O/AN fuel was 269 K (−4 °C), and the density at 298 K (25 °C) was 1.34 g/mL. Strand-burning rates of the EAN/B/H<sub>2</sub>O/AN fuel were determined in both glass and combustible straws between 0.79 and 17.3 MPa (100 and 2500 psia) and ranged from 2.3 mm/s (0.09 in./s) at 0.79 MPa to 18.8 mm/s (0.74 in./s) at 17.3 MPa. Even though the pressure exponent was relatively high (0.918), this should be no problem for a liquid bipropellant engine in which the propellant is injected as an aerosol spray. Flashback characterization tests where the propellant was pumped continuously from the bottom of a 3.9-mm ID tube showed that the flame front propagated upstream at a rate of 5 mm/s. The flame front did not propagate upstream when a capillary tube 1.75 mm in diameter was inserted into the feed tube.

The thermophysical properties (densities, electric conductivities, and viscosities) of ethylammonium, propylammonium, and butylammonium nitrate ionic liquids and their binary mixtures were determined at atmospheric pressure in the range  $288 < T < 353$  K [137]. Measurements of primary amine nitrates were followed by studies of binary mixtures composed of ethylammonium nitrate (with three hydrogen-bond donor groups) and different homologous ionic liquids with differing numbers of hydrogen-bond donor groups: diethylammonium nitrate (two hydrogen-bond donors), triethylammonium nitrate (one hydrogen-bond donor), and tetraethylammonium nitrate (no hydrogen-bond donors). The results showed a quasi-ideal behavior for all monoalkylammonium nitrate mixtures. In contrast, the other mixtures showed deviations from ideality, namely when the difference in the number of carbon atoms present in the cations increased or the number of hydrogen-bond donors present in the cation decreased. Besides the length and distribution of alkyl chains present in a cation such as alkylammonium, there are other structural and interaction parameters that influence the thermophysical properties of pure compounds and their mixtures.

### 3.7.2.1 Reactions of Diethylammonium Nitrate

The most undesirable reactions of diethylammonium nitrate are those leading to nitrosamines, which are active carcinogens [138]. Such reactions could occur in the dribble volume of bipropellant engines operating on fuels containing diethylamine.

### 3.7.2.2 Physical Properties of Triethylammonium Nitrate

Based on DSC data, the heat capacity of solid triethylammonium nitrate at 348 K (75 °C) is  $1.6 \pm 0.2$  J g<sup>−1</sup> K<sup>−1</sup>. The melting point is at 387 K (114 °C), and the heat of fusion is  $61.3 \pm 1$  J/g = 10.066 kJ/mol [18]. Physical properties of triethylammonium nitrate are summarized in Table 34.

**Table 34:** Physical properties of triethylammonium nitrate.

| Property       | at ... K | SI units                                      | Other units   |                |
|----------------|----------|-----------------------------------------------|---------------|----------------|
| Molecular mass |          | 164.203 g/mol                                 | 6.090 mol/kg  | —              |
| Oxygen balance |          | −165.6%                                       | —             | —              |
| Melting point  |          | 387 K                                         | 114 °C        | —              |
| Heat capacity  | 348      | $1.6 \pm 0.2 \text{ J g}^{-1} \text{ K}^{-1}$ | —             | —              |
| Heat of fusion |          | $61.3 \pm 1 \text{ J/g}$                      | 10.066 kJ/mol | 2.405 kcal/mol |

The apparent molar volume and the partial molar volume of solvent and solute of diethylammonium nitrate and triethylammonium nitrate were derived from density measurements of aqueous solutions of these salts in the concentration range 0.01–0.5 mol/kg for the temperature range of 288 to 303 K and at 101 kPa [139]. These product ionic liquids were also characterized by  $^1\text{H}$  NMR spectra.

### 3.7.3 Thermal Stability of Mono-, Di-, and Triethylammonium Nitrates

Based on DSC data of solid triethylammonium nitrate [18], the preexponential factor of the decomposition rate equation is  $10^{13.73}$ , and the activation energy is 140.3 kJ/mol.

### 3.7.4 Physical Properties of Tetraethylammonium Nitrate

The standard enthalpy of formation of crystalline tetraethylammonium nitrate is  $-428.5 \pm 4 \text{ kJ/mol}$  [16]. That of the corresponding crystalline tetraethylammonium azide is  $+58.6 \pm 4.1 \text{ kJ/mol}$ .

### 3.7.5 Thermal Stability of Mono-, Di-, Tri-, and Tetraethylammonium Perchlorates

The thermal decomposition of ethylammonium perchlorate and isopropylammonium perchlorate has been studied using DTA, TGA, and isothermal weight-loss measurements, and the decomposition products were analyzed in a mass spectrometer [36]. The proton-transfer dissociation mechanism proposed earlier for the thermal decomposition of AP has been extended to explain the decomposition products of these two substituted ammonium perchlorates.

Triethylammonium perchlorate has a molecular mass of 201.6 g/mol, melts at  $349 \text{ K} = 76^\circ\text{C} = 169^\circ\text{F}$ , and has a heat of combustion of  $9236 \text{ BTU/lb} = 5131 \text{ cal/g} = 1034 \text{ kcal/mol} = 4328 \text{ kJ/mol}$ .

The thermal stability of tetraethylammonium perchlorate was investigated using TGA, DTA, and mass spectrometric analysis of the decomposition products [140]. It was found that tetraethylammonium perchlorate undergoes a crystallographic phase change at  $371 \text{ K} (98^\circ\text{C})$ . The heat of phase transformation was calculated to be  $10.46 \text{ kJ/mol} (2.5 \text{ kcal/mol})$ . The mass spectral data suggest that the salt undergoes thermal decomposition into neutral particles, which are then vaporized and ionized as well as oxidized. It will explode at  $571 \text{ K} (298^\circ\text{C})$ .

## 4 Propylamines

There are two known propylamines: *n*-propylamine, 1-propanamine, CAS RN [107-10-8], and isopropylamine, 2-propanamine. Their physical properties are very similar and are summarized in [9]. There are no known industrial applications of these propylamines other than the temporary use of their nitrate salts in liquid gun propellants such as NOS365.

*n*-Propylamine has been tested as an additive to furfuryl alcohol in an effort to shorten the hypergolic ignition delays of either one [141].

### 4.1 Physical Properties of Propylamines

Isopropylamine is not likely to be used as a rocket propellant; nevertheless, viscosity data at high pressure have been measured for this fuel (Table 35). This viscosity can be compared to other alkylamines that actually have been used as rocket fuels.

**Table 35:** Viscosity of isopropylamine.

| Temperature |    | Viscosity, cPs |        |        |        |        |        |
|-------------|----|----------------|--------|--------|--------|--------|--------|
| K           | °C | Pressure, atm  |        |        |        |        |        |
|             |    | Bubble point   | 50     | 100    | 150    | 200    | 250    |

Data source: [142–144]

### 4.2 Propylammonium Nitrates

*n*-Propylammonium nitrate,  $C_3H_{10}N_2O_3$ , CAS RN [22113-88-8],  $M = 122.125$  g/mol, and its isomer, isopropylammonium nitrate, have been considered as fuels for HAN-based monopropellants.

#### 4.2.1 Physical Properties of Propylammonium Nitrates

*n*-Propylammonium nitrate is a room-temperature ionic liquid that melts at 276.6 K (3.5°C) and has a density of 1.16 g/cm<sup>3</sup>.

#### 4.2.2 Thermal Stability of Propylammonium Nitrates

Based on DSC data, the heat capacity of solid isopropylammonium nitrate (IPAN) at 338 K (65 °C) is  $1.4 \pm 0.2 \text{ J g}^{-1} \text{ K}^{-1}$ . The melting point is at 346 K (73 °C), and the heat of fusion is  $16.12 \text{ kJ/mol} = 132 \pm 2 \text{ J/g}$  [18, 145]. In the range between 448 and 563 K (175 and 290 °C), several endothermic and exothermic peaks overlap. At 423 K (150 °C) it is possible to detect subliming, undecomposed IPAN in the vapor phase.

Based on DSC data, the heat capacity of solid diisopropylammonium nitrate at 403 K (130 °C) is  $2.1 \pm 0.3 \text{ J g}^{-1} \text{ K}^{-1}$ . The melting point is at 461 K (188 °C), but the heat of fusion could not be determined because the chemical began to decompose on melting [18]. There were crystalline phase transitions in the solid state, and the crystals may also have contained water as crystalline hydrates. These peaks overlapped. The IR spectra of the gas space above the melting sample revealed the presence of water,  $\text{N}_2\text{O}$ ,  $\text{CO}_2$ , acetone, and propene.

#### 4.3 Propylammonium Perchlorates

The thermal decomposition of isopropylammonium perchlorate has been studied using DTA, TGA, and isothermal weight-loss measurements, and the decomposition products were analyzed in a mass spectrometer [36]. The proton-transfer dissociation mechanism proposed earlier for the thermal decomposition of AP has been extended to explain the decomposition products of isopropylammonium perchlorate.

### 5 Amines with Large Alkyl Groups

The higher alkylamines from C3 (propylamine) on up are not readily available in industrial quantities, do not offer any advantages over ethylamines, and are not considered as preferred fuels for rocket propulsion.

**Table 36:** Enthalpies of formation of butylamines.

| Compound                 | Formula                                 | Molecular mass |        | Enthalpy of formation $\Delta H_f^{298}$ |       |          | Density $\rho$    |                    | References |
|--------------------------|-----------------------------------------|----------------|--------|------------------------------------------|-------|----------|-------------------|--------------------|------------|
|                          |                                         | g/mol          | mol/kg | kJ/mol                                   | cal/g | kcal/mol | g/cm <sup>3</sup> | lb/in <sup>3</sup> |            |
| <i>n</i> -Butylamine     | $\text{C}_4\text{H}_9\text{NH}_2$       | 73.14          | 13.67  | −128                                     | −417  | −30.5    | 0.7501            | 0.0271             | [27]       |

| Tri-iso-butyl-amine      | $\text{C}_{12}\text{H}_{25}\text{NH}_2$ | 185.36         | 5.39   | −316                                     | −408  | −75.6    | 0.7695            | 0.0278             | [27]       |
| <i>n</i> -Butylamine     | $\text{C}_4\text{H}_9\text{NH}_2$       | 73.14          | 13.67  | −128                                     | −417  | −30.53   | —                 | —                  | [17]       |
| <i>tert</i> -Butyl-amine | $\text{C}_4\text{H}_9\text{NH}_2$       | 73.14          | 13.67  | −150.4                                   | −492  | −35.95   | —                 | —                  | [17]       |

A series of primary, secondary, and tertiary alkylamines has been used in an academic study to clarify the relationship between ignition delay in a hypergolic propellant rocket engine and the molecular structure and heat of neutralization of alkylamines [146, 147]. It was noted that the ignition delay decreased from ethylamine to *n*-amyl amine although the viscosity increased. In spite of their shorter ignition delays, the higher alkylamines are not used as rocket propellants. The enthalpies of formation of three liquid butylamines were listed in [27] (Table 36).

### 5.1 Butylammonium Nitrates

There are at least three different butylammonium nitrates, all structural isomers. All share the same gross formula of  $C_4H_{12}N_2O_3$  and the molecular mass of 136.15 g/mol. Based on DSC data, the heat capacity of solid *tert*-butylammonium nitrate at 373 K (100 °C) is  $1.9 \pm 0.3 \text{ J g}^{-1} \text{ K}^{-1}$ . The melting point is at 412 K (139 °C), and the enthalpy of fusion is  $72 \pm 1 \text{ J/g} = 9.79 \text{ kJ/mol}$  [18]. Sublimation is dominant at 473–543 K (200–280 °C), and the enthalpy of sublimation is  $\sim 1020 \text{ J/g}$ .

*n*-Butylammonium nitrate is of interest as an ionic liquid but not necessarily as a rocket propellant [148]. The density and viscosity of the pure ionic liquid *n*-butylammonium nitrate and its binary mixtures with methanol, ethanol, 1-propanol, and 1-butanol were measured at temperatures ranging from 293.15 to 313.15 K. The thermal expansion coefficient, molecular volume, standard entropy, and lattice energy of *n*-butylammonium nitrate were deduced from experimental density results.

Tetra-*n*-butylammonium trinitromethanide is well crystallized, and its crystal structure was determined by XRD, supported by  $^{13}\text{C}$  and  $^{14}\text{N}$  NMR spectra [149].

### 5.2 C>6 Alkylammonium Salts

Most salts of lower ( $C < 3$ ) alkylamines are polar, saline compounds with poor solubility in organic binders prepolymers used in solid propellants. Alkylammonium salts with at least one longer carbon chain have improved solubility and can be added to solid propellant binders (requiring less oxidizer) or can be used as bonding agents to coat AP crystals prior to incorporating them into a composite propellant. Compounds in this category include cetyl trimethylammonium perchlorate  $\text{CH}_3(\text{CH}_2)_{15}\text{N}^+(\text{CH}_3)_3\text{ClO}_4^-$ , which melts at 385 K (112 °C) and decomposes with two exothermic peaks, one at 428 K (155 °C) and another at 523 K (250 °C) [150].

## 6 Imines with One Nitrogen Atom

Imines are heterocyclic secondary amines in which two of the hydrogens of ammonia are replaced by the ends of an alkylene chain. They can be considered as ring-closed saturated secondary amines. Among the imines with the general molecular structure  $(\text{CH}_2)_n\text{NH}$ , the lowest member with a strained ring structure, ethylene imine ( $n=2$ ), and a higher member, piperidine ( $n=5$ ), have been considered as rocket propellants. Heterocyclic ring structures with one to five nitrogen atoms in the rings that also contain double bonds are discussed here in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic and Heterocycloaliphatic Amines.” Ethylene imine would fit here under amines or under heterocyclic compounds. The discussion of ethylene imine has been moved to three-membered rings and therefore is also discussed in the chapter “Heterocyclic and Heterocycloaliphatic Amines.”

## 7 Saturated Open-Chain Aliphatic Amines with More than One Nitrogen Atom in the Molecule

Saturated open-chain aliphatic amines with more than one nitrogen atom in the molecule could be called multifunctional amines.

### 7.1 Ethylenediamine

Ethylenediamine, also known as 1,2-diaminoethane,  $\text{H}_2\text{N}-\text{CH}_2-\text{CH}_2-\text{NH}_2$ ,  $\text{C}_2\text{H}_8\text{N}_2$ , CAS RN [107-15-3], often abbreviated as EDA, is a colorless, viscous, hygroscopic liquid that fumes in moist air. Like some of the other amines, it has the typical fishy odor. It is a relatively strong base, and when spilled on unprotected skin, it can be quite irritating. The gross formula of EDA is the same as that of UDMH, but its performance as a rocket fuel is not as good. Properties of EDA are summarized here because it can be used as an ingredient in hypergolic fuel mixtures, and it is the feed stock for making ethylenediamine dinitrate, an explosive and propellant ingredient. The dinitrate salt of EDA is often abbreviated as EDDN, and it has been used as an explosive. A separate section describes the properties of EDDN.

Ethylenediamine can be synthesized by reaction of 1,2-dichloroethane with ammonia. This reaction also produces diethylene triamine  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHC}_2\text{H}_4\text{NH}_2$  and piperazine  $\text{HN}(\text{CH}_2\text{CH}_2)_2\text{NH}$  as by-products.

Ethylenediamine is the amine that is commonly used as a sensitizer for binary nitromethane explosives (PLX).

### 7.1.1 Physical Properties of Ethylenediamine

The physical properties of ethylenediamine are summarized in Table 37.

**Table 37:** Physical properties of ethylenediamine.

| Property                                                     | SI units                 | Non-SI units                        | References |
|--------------------------------------------------------------|--------------------------|-------------------------------------|------------|
| Freezing point                                               | 284.15 K                 | +11 °C                              | [29]       |
| Boiling point                                                | 391 ± 1 K                | 118 ± 1 °C                          | [29]       |
| Density                                                      | 899.4 kg/m <sup>3</sup>  | 0.8994 g/cm <sup>3</sup> (20 °C)    | [119]      |
| Viscosity                                                    | See separate table below |                                     |            |
| Critical temperature                                         | 613.1 K                  | 340 °C                              | [29]       |
| Critical pressure                                            | 67.07 bar                | 66.19 atm                           | [29]       |
| Standard enthalpy of formation<br>( $\Delta H_f^{298}$ ) (L) | −26.6 kJ/mol             | −6.36 kcal/mol <sup>a</sup>         | [17]       |
|                                                              | −63.01 ± 0.54 kJ/mol     | −15.06 ± 0.13 kcal/mol <sup>a</sup> | [29]       |
| Standard enthalpy of formation<br>( $\Delta H_f^{298}$ ) (G) | −17.0 ± 0.59 kJ/mol      | −4.06 ± 0.14 kcal/mol               | [29]       |
| Enthalpy of vaporization at NBP                              | 37.98 kJ/mol             | 9.08 kcal/mol                       | [29]       |
| Index of refraction, $n_D^{26}$                              | 1.4540                   | —                                   | [119]      |

<sup>a</sup> The data from Stull, Westrum, and Sinke [6] and NIST Chemistry WebBook [29] are quite different

Ethylenediamine could potentially be used as a rocket fuel along with other alkylamines. The viscosity of ethylenediamine and ethylenediamine hydrate in the liquid phase was measured with a steel rolling-ball viscometer over the temperature range of 303 to 488 K (30 to 210 °C) [142]. The viscosity of ethylenediamine hydrate was substantially higher than that of the anhydrous amine [143, 144]. The data are summarized in Table 38.

**Table 38:** Viscosity of ethylenediamine.

| Temperature |    | Viscosity, cPs |       |       |       |       |       |
|-------------|----|----------------|-------|-------|-------|-------|-------|
| K           | °C | Pressure, atm  |       |       |       |       |       |
|             |    | Bubble point   | 50    | 100   | 150   | 200   | 250   |
| 303         | 30 | 1.586          | 1.632 | 1.889 | 1.720 | 1.760 | 1.789 |
| 313         | 40 | 1.260          | 1.292 | 1.328 | 1.364 | 1.392 | 1.412 |
| 323         | 50 | 1.033          | 1.053 | 1.082 | 1.116 | 1.140 | 1.18  |

Data source: [144]

The vapor pressure of ethylenediamine in the temperature range of 299 to 391 K can be calculated from an Antoine equation:

$$\log P = A - [B/(T + C)] = 4.22368 - [1302.256/(T - 81.788)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin [29].

The IR spectrum of an ethylenediamine solution in  $\text{CCl}_4$  or  $\text{CS}_2$  is shown in Figure 4. Although EDA is not used as a rocket propellant, the IR spectrum of EDA is shown here so that it can be compared to the IR spectrum of its dinitrate salt.

**Figure 4:** IR spectrum of ethylenediamine. (Reproduced and modified with permission from [151])

### 7.1.2 Toxicity of Ethylenediamine

The conversion factor for permissible exposure limits of ethylene diamine in air is  $1\text{ ppm} = 2.46\text{ mg/m}^3$  at  $25^\circ\text{C}$  and  $1\text{ atm}$ . The NIOSH REL TWA exposure limit for ethylenediamine is  $10\text{ ppm}$  ( $25\text{ mg/m}^3$ ), the same as the OSHA PEL TWA of  $10\text{ ppm}$  ( $25\text{ mg/m}^3$ ). The ACGIH TLV is  $10\text{ ppm}$  ( $25\text{ mg/m}^3$ ). The original IDLH of EDA was  $2000\text{ ppm}$ , but it was lowered to  $1000\text{ ppm}$  a few years later. The chosen IDLH was based on a report that an 8-h exposure to  $4000\text{ ppm}$  EDA killed six of six rats, but an 8-h exposure to  $2000\text{ ppm}$  killed zero of six rats. Ethylenediamine is corrosive to the eyes, skin, and respiratory tract. Skin contact can cause blistering. Eye contact can cause pain, serious injury, and permanent damage. Prolonged inhalation can cause pulmonary edema, a medical emergency that can be delayed for several hours and can be fatal.

Ethylenediamine ended up being listed on the European Chemicals Agency (ECHA) Candidate List of Substances of Very High Concern for Authorisation on 27 June 2018 because of its respiratory sensitizing properties.

### 7.1.3 Flammability of Ethylenediamine

The flammable range of EDA vapors at 373 K (100 °C = 212 °F) is 2.5–12 vol-%. The flash point is 307 K (34 °C = 93 °F) [152].

### 7.1.4 Salts of Ethylenediamine

#### 7.1.4.1 Ethylenediammonium(2+) Dinitrate

The correct name for ethylenediamine dinitrate,  $[\text{H}_3\text{N}^+\text{CH}_2\text{CH}_2\text{N}^+\text{H}_3][\text{NO}_3^-]_2$ , CAS RN [20829-66-7], would be 1,2-ethanediammonium dinitrate, often abbreviated as EDDN. Alternate names would be ethylenediammonium(2+) dinitrate or 1,2-ethanediamine nitrate (1:2). It may also be called ethylenediaminium dinitrate. It is prepared by neutralizing an aqueous solution of ethylenediamine with dilute nitric acid, driving off the water and crystallization from the concentrated solution. The dry salt is somewhat hygroscopic and readily soluble in water. It melts at 461 K (188 °C). Ethylenediamine dinitrate is an energetic material that is often used as an ingredient in melt-cast explosives. It can also be used in solid propellants. Its oxygen balance for combustion to carbon dioxide is -25.8%; therefore, it is a fuel but nearly stoichiometrically oxidized, and thus it does not need much additional oxidizer to achieve complete combustion to carbon monoxide or carbon dioxide.

The preparation of EDDN is a simple acid–base neutralization reaction:

Ethylenediammonium(2+) dinitrate in eutectic mixtures with ammonium nitrate and potassium nitrate can be used as a castable, intermolecular explosive [153].

#### Physical Properties of Ethylenediammonium(2+) Dinitrate

In an effort to find replacements for EDDN with improved thermal stability, a wide range of nitrate salts of other diamines and polyamines was investigated in a study called “Synthesis and Properties of Selected Energetic Organodi- and Polyammonium Nitrate Salts” [21, 154]. The objective of this program was to synthesize and characterize selected organodi- and polyammonium nitrate salts for use in a study of thermal and impact stability characteristics. A total of 22 nitrate salts were prepared and characterized, 15 of which had never been reported in the literature. The list included homologues of EDDN, as well as *N*- and *N,N'*- mono-, di-, tri-, and tetrasubstituted ethylenediamines and their nitrates. The compounds were characterized by elemental analyses and drop-weight sensitivity as well as by their NMR spectra. Other data generated were densities (calculated and measured), heats of fusion, melting points, and the temperature of the major peak associated with

exothermic decomposition as measured by DSC. Thermal stability decreased with increasing chain length, N-substitution of the amines, and molecular weight.

The physical properties of EDDN are summarized in Table 39, and an IR spectrum is shown in Figure 5.

**Table 39:** Physical properties of ethylenediammonium(2+) dinitrate

| Property              | SI units               |               | Other units             |                          | References |
|-----------------------|------------------------|---------------|-------------------------|--------------------------|------------|
| Molecular mass        | 186.124 g/mol          | 5.3735 mol/kg | —                       | —                        |            |
| Melting point         | 461 K                  | —             | 188 °C                  | 370 °F                   | [15]       |
|                       | 457 K                  | —             | 184 °C                  | —                        | [155]      |

**Figure 5:** Infrared spectrum of ethylenediammonium(2+) dinitrate. (Reproduced and modified from [155].)

### Chemical Properties of Ethylenediammonium(2+) Dinitrate

Ethylenediamine dinitrate is somewhat hygroscopic and is readily soluble in water. See also [156].

### Thermal Stability of Ethylenediammonium(2+) Dinitrate

The species evolving during rapid thermolysis of solid EDDN were analyzed by rapid scanning FTIR spectrometry, with a complete scan performed every 100 ms [157]. This combination of DTA and product analysis is a good method to “unravel” an energetic molecule step by step and identify the weak spots in a molecule where the reaction starts first. The rapid thermolysis of 2-mg samples of solid EDDN at a heating rate of

70 K/s under 103 kPa (15 psi) argon showed a very complex behavior compared to HAN and HN, which were investigated at the same time. After melting, the temperature rises to 280 °C before decomposition products are detectable. The initial endotherm at 353 K (80 °C) leads to proton transfer and release of  $\text{HNO}_3$ . Between 548 and 603 K (275 and 330 °C) the decomposition is endothermic, and above 603 K (330 °C) it becomes exothermic and combustion products of the molecule appear: nitric acid first, followed by  $\text{NO}_2$ ,  $\text{NH}_3$ ,  $\text{N}_2\text{O}$ , and, finally,  $\text{CO}_2$  and  $\text{HCN}$ . N—H and C—N bonds are broken before the C—C bonds. A strong exotherm follows, starting at 373 K (100 °C) [158–160]. EDDN mixtures with AN are more thermally stable than EDDN alone, and they have better explosive performance than AN alone. The eutectic mixture has a lower melting point than either component, making it suitable for melt casting. However, EDDN/AN mixtures suffer from volume changes with temperature because of the phase transitions of AN. The addition of potassium nitrate stabilizes the AN and counters the expansion of AN at 305 K (32 °C) caused by one of the solid–solid phase transitions.

Studying the fast thermal decomposition of five *N*-methyl substituted ethanediammonium dinitrate salts, it was noted that the thermal decomposition behavior of most of these compounds more closely resembles that of alkylammonium mononitrate salts than primary alkanediammonium dinitrate salts (e.g., EDDN). Only the *N,N,N',N'*-tetramethylethanediammonium dinitrate behaved similarly to EDDN [161]. The behavior of *N*-methylethylenediammonium dinitrate MEDD, *N,N,N',N'*-tetramethyl-ethylene diammonium dinitrate TMEDD, *N,N,N'*-trimethylethylenediammonium dinitrate TRMEDD, *N,N'*-dimethylethanediammonium dinitrate, *sym*-DMEDD, and *N,N'*-dimethylethanediammonium dinitrate *unsym*-DMEDD more closely resembled the behavior of alkylammonium mononitrate salts in terms of the temperature at which  $\text{HNO}_3$  was released. The first decomposition step of most primary and secondary alkylammonium nitrate salts is the production of  $\text{HNO}_3(\text{G})$ . See also [162].

### Strand-Burning Rates of Solid Ethylenediammonium(2+) Dinitrate

EDDN was compared with ethylenediamine diperchlorate and carbonylhydrazide nitrate in a study of the effect of the molecular structure of energetic materials on the burning rate [163].

### Safety Properties of Ethylenediammonium(2+) Dinitrate

The impact sensitivity of EDDN is 10 Nm when tested in the BAM apparatus. In the BAM friction test apparatus, friction sensitivity of EDDN is above 353 N pistil load, which gave no reaction at the upper load limit of the machine.

### Explosive Performance of Ethylenediammonium(2+) Dinitrate

In the lead block test, if a 10-g sample of EDDN explodes, it will enlarge the cavity so that it will hold  $350\text{ cm}^3$  of water. The detonation velocity of confined and densely pressed EDDN is 6800 m/s at a packing density of  $1.53\text{ g/cm}^3$ .

### Applications of Ethylenediammonium(2+) Dinitrate

EDDN forms a eutectic with diethylenetriammonium(3+) trinitrate (DETN), melting between 460.7 and 461.3 K (187.6 and 188.2°C) when it was being tested as a melt-cast explosive and as a replacement for Composition B in mortar rounds and bomb fills [164].

EDDN forms a eutectic mixture (melting point 373 K = 100°C = 212°F) when mixed with an equal amount of AN. This mixture is a potential melt-cast explosive.

#### 7.1.4.2 Ethylenediammonium(2+) Diperchlorate

Ethylenediamine forms a monopерchlorate from ethylene diamine and perchloric acid in 1:1 molar proportions and a dipерchlorate salt with an excess of perchloric acid [165].

Ethylenediammonium(1+) перchlorate (ethylenediamine monopерchlorate, gross formula  $C_2H_9N_2O_4Cl$ , CAS RN [25682-07-9]) is less frequently worked with.

Ethylenediammonium(2+) dipерchlorate, EDDP, ethylenediamine dipерchlorate, gross formula  $C_2H_{10}N_2O_8Cl_2$ , molecular mass 261.015 g/mol, CAS RN [15718-71-5], is an energetic material that has been considered as an ingredient in melt-cast explosives. It can also be used in solid propellants. Its oxygen balance is zero, thus it is stoichiometrically oxidized, and it does not need any additional oxidizer to achieve complete combustion to carbon dioxide and water. EDDP can be prepared by slowly neutralizing 20%  $HClO_4$  with ethylene diamine diluted with an equal amount of water and slowly concentrating the resulting solution by evaporation.

#### Physical Properties of Ethylenediammonium(2+) Diperchlorate

The IR spectrum of ethylenediammonium(2+) dipерchlorate exhibited characteristic bands due to the  $NH_3^+$  group at 3400(s), 3180(s) ( $\nu NH_3$ ), and  $1588\text{ cm}^{-1}$  ( $\delta NH_3$ ). The absorptions at 1065(s), 942(w), and 620(s) are characteristic of the  $ClO_4^-$  group.

Tables 10, 11, and 12 summarize the physical properties of ethylenediammonium dipерchlorate and its hemihydrate.

Ethylenediammonium(2+) dipерchlorate and triethylenediammonium(2+) dipерchlorate cocrystallize, and single crystals were grown from solution and characterized by  $^1H$  NMR and single-crystal XRD [166]. The results confirmed that the molar ratio of ethylenediamine to triethylenediamine is 1:1. The crystal belongs to the orthorhombic system, space group  $Cmc2_1$  with  $a = 0.8103(16)\text{ nm}$ ,  $b = 2.4725(5)\text{ nm}$ ,  $c = 1.0195(2)\text{ nm}$ ,  $V = 2.0425(7)\text{ nm}^3$ ,  $Z = 8$ , and  $\rho_{XRD} = 1.828\text{ g/cm}^3$ . The molecular structure of the co-crystals is held together by hydrogen bonding.

#### Chemical Properties of Ethylenediammonium(2+) Diperchlorate

Ethylenediammonium dipерchlorate is a potential explosive and propellant ingredient. It forms a hemihydrate that, based on DTA data with a heating rate of 20 K/min, undergoes a reversible phase transition at 368 K (95°C) and loses water at 393–403 K

(120–130 °C) to form the anhydrous salt, which eventually decomposes when the temperature increases to 563 K (290 °C).

### Thermal Stability of Ethylenediammonium(2+) Diperchlorate

The TGA plot indicated that decomposition takes place in two stages in the temperature ranges of 275–310 and 320–365 °C. No residue remained at 365 °C; the whole material was oxidized to gaseous products. The weight loss observed at the end of the first stage of decomposition was 61% [167]. The DTA showed two exothermic effects peaking at 573 and 631 K (300 and 358 °C). Initially a proton transfer takes place at 548–583 K (275–310 °C), and later the entire material is oxidized to form gaseous products.

The thermal decomposition of ethylene diamine diperchlorate (EDDP) has been studied using DTA, TGA, isothermal weight-loss measurements, and mass-spectrometric analysis of the decomposition products [168]. EDDP decomposed in two temperature regions. The low-temperature decomposition stopped at about 35 to 40% weight loss below 523 K (250 °C). An overall activation energy of 54 kcal/mol was calculated for the thermal decomposition of EDDP. Mass-spectrometric analysis showed that the decomposition products were mainly CO<sub>2</sub>, H<sub>2</sub>O, HCl, and N<sub>2</sub>. The following stoichiometry has been proposed for the thermal decomposition of EDDP:

### Strand-Burning Rates of Solid Ethylenediammonium Diperchlorate

The strand-burning rate of EDDP has been compared to that of 1,4-butanediammonium diperchlorate and *p*-phenylenediammonium diperchlorate [169]. The three organic perchlorates

- ethylenediammonium diperchlorate (CH<sub>2</sub>NH<sub>2</sub>•HClO<sub>4</sub>)<sub>2</sub>,
- tetramethylenediammonium diperchlorate (CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>•HClO<sub>4</sub>)<sub>2</sub>, and
- *p*-phenylenediammonium diperchlorate O<sub>4</sub>ClH•H<sub>2</sub>N–C<sub>6</sub>H<sub>4</sub>–NH<sub>2</sub>•HClO<sub>4</sub>

differ from one another, both with respect to the structure of the organic part of the molecule and to the heat of explosion. The substances were obtained through the reaction of amines with a 40% excess of 60% HClO<sub>4</sub> beyond that required for the stoichiometric diperchlorate salt. Of the three perchlorates under consideration, *p*-phenylenediamine diperchlorate had the most rapid rate of combustion. EDDP burned somewhat more slowly and considerably more stably than did *p*-phenylenediamine diperchlorate. The rate of combustion at atmospheric pressure was 0.1 cm/s; up to 20 atm, it increased according to the equation

$$r_b = -0.13 + 0.23p^{0.68}$$

and in the interval from 20 to 400 atm

$$r_b = 0.14p^{0.85},$$

where  $r_b$  is the burning rate in cm/s and  $p$  is the pressure in atmospheres. EDDP was compared with EDDN and carbohydrazide nitrate in a study on the effect of the molecular structure of energetic materials on the burning rate [163].

### Detonability of Ethylenediammonium Diperchlorate Solutions

The detonability of aqueous solutions/suspensions of organic amine perchlorates was studied in steel and glass ampoules with an electric detonator with or without an intermediate hexogen booster. The detonation temperature of aqueous solutions of EDDP was 2160–2220 K, and the concentration limit of H<sub>2</sub>O below which the solutions retained their detonation capacity was 21–24% H<sub>2</sub>O [95]. Similar data for ethylenediammonium monoperochlorate solutions included a detonation temperature of 1820–1960 K, and the concentration limit of H<sub>2</sub>O below which the solutions retained their detonation capacity was 39–42% H<sub>2</sub>O.

### Mixtures Containing Ethylenediammonium(2+) Diperchlorate

Ethylenediammonium(2+) diperchlorate forms a double salt with triethylenediammonium(2+) diperchlorate, which is a very energetic and very sensitive compound with a well-defined crystal structure. The molecular and crystal structures of ethylenediammonium(2+) triethylenediammonium(2+) tetraperochlorate have been determined by XRD [170]. The compound crystallized in the orthorhombic system (space group *Cmc*<sub>21</sub>) with cell dimensions  $a = 8.1030$ ,  $b = 24.725$ , and  $c = 10.195$  Å [171].

#### 7.1.4.3 Ethylenediammonium(2+) Bisdinitramide

Ethylenediamine (1,2-diaminoethane) forms a diprotonated salt with dinitramidic acid, ethylenediammonium(2+) bisdinitramide, C<sub>2</sub>H<sub>10</sub>N<sub>8</sub>O<sub>8</sub>, CAS RN [165603-96-3], which is of interest as an energetic additive to propellants and gas generants. Ethane diammonium bis(dinitramide) melts at 398 K (125 °C) [172]. The salt crystallizes in the triclinic space group *P*1 with cell dimensions  $a = 5.614(1)$ ,  $b = 6.867(2)$ ,  $c = 7.371(2)$  Å,  $\alpha = 68.89(2)$ ,  $\beta = 89.00(2)$ ,  $\gamma = 78.90(2)^\circ$ ,  $Z = 1$ , and  $\rho_c = 1.753$  g/cm<sup>3</sup> [173]. Atomic coordinates, bond lengths and angles, and equivalent isotropic displacement parameters for the salt have been calculated and tabulated. These cations provide a constrained local environment for the dinitramide anions due to extensive hydrogen bonding.

The enthalpy of formation of ethylenediammonium dinitramide (dinitramidate) is  $-194.6 \pm 1.8$  kJ/mol ( $-46.52 \pm 0.43$  kcal/mol) [117]. Other sources gave an enthalpy of formation of ethylenediamine bisdinitramide of  $-209$  kJ/mol ( $-49.9$  kcal/mol) [98].

#### 7.1.4.4 Ethylenediammonium(2+) Salts of Other Acids

Ethylene diamine forms an ethylenediammonium salt with 5-nitrotetrazole C<sub>4</sub>H<sub>10</sub>N<sub>12</sub>O<sub>4</sub> that is of interest as an energetic material. It melts at 494 K (221 °C) and has a density of 1.65 g/cm<sup>3</sup>. It is thermally stable up to 489 K (216 °C). Its enthalpy of formation is +233 kJ/mol (+55.7 kcal/mol). Its drop-weight sensitivity is 42 cm (type 12 tool). The ethylenediammonium salt of 5-nitrotetrazole forms a eutectic

with AN that is of interest as a melt-castable explosive [174, 175]. Moreover, this eutectic mixture, which contains 87.8 mol-% (66.5 mass-%) of AN, is close to the CO<sub>2</sub>-balanced composition of 90 mol-% and has a relatively low melting point of 383.6 K (110.5°C), making it readily castable. A ternary blend containing 26.33 mass-% ethylenediammonium salt of 5-nitrotetrazole, 47.54 mass-% AN, and 26.13 mass-% EDDN melts even lower, at 362.6 K (89.5°C) [176].

The ethylenediammonium(2+) salt of 3-nitro-1,2,4-triazol-5-one (NTO), C<sub>2</sub>H<sub>4</sub>(NH<sub>3</sub>)<sub>2</sub>•2C<sub>2</sub>H<sub>1</sub>N<sub>4</sub>O<sub>3</sub>, molecular mass 320.22 g/mol, crystallized in triclinic crystals, space group  $P\bar{1}$  with the cell parameters  $a = 6.528(3) \text{ \AA}$ ,  $b = 10.780(2) \text{ \AA}$ ,  $c = 14.236(3) \text{ \AA}$ ,  $\alpha = 81.11(2)^\circ$ ,  $\beta = 87.13(3)^\circ$ ,  $\gamma = 74.05(3)^\circ$ ,  $V = 951.73 \text{ \AA}^3$ ,  $Z = 3$ , and  $\rho = 1.676 \text{ g/cm}^3$  [177].

The ethylenediammonium(2+), ammonium, hydrazinium(1+), and guanidinium salts of NTO were synthesized and characterized [178]. Small-scale sensitivity tests indicated that these compounds are thermally stable and only moderately insensitive to impact.

Well-crystallized ethylenediammonium(2+) salts are formed from ethylenediamine and mono-, di-, and trinitrophenolates (picrates) [179]. Their structures were characterized and confirmed by <sup>1</sup>H and <sup>13</sup>C NMR, IR spectroscopy, and elemental analysis.

#### 7.1.4.5 Ethylenediamine as a Ligand in Metal Complexes

Being a bidentate ligand (similar to hydrazine), ethylenediamine forms a wide array of complexes with transition metals. Such complexes with oxidizing anions (nitrate, perchlorate) have been considered as energetic additives or even as primary explosives.

Ten transition-metal nitrate and perchlorate complexes of hydrazine and ethylenediamine (EN) were synthesized, namely [Cu(EN)<sub>2</sub>](ClO<sub>4</sub>)<sub>2</sub>, [Co(EN)<sub>3</sub>](ClO<sub>4</sub>)<sub>3</sub>, [Ni(EN)<sub>3</sub>](ClO<sub>4</sub>)<sub>2</sub>, [Hg(EN)<sub>2</sub>](ClO<sub>4</sub>)<sub>2</sub>, [Cr(N<sub>2</sub>H<sub>4</sub>)<sub>3</sub>](ClO<sub>4</sub>)<sub>3</sub>, [Cd(N<sub>2</sub>H<sub>4</sub>)<sub>3</sub>](ClO<sub>4</sub>)<sub>2</sub>, [Ni(N<sub>2</sub>H<sub>4</sub>)<sub>3</sub>](NO<sub>3</sub>)<sub>2</sub>, [Co(N<sub>2</sub>H<sub>4</sub>)<sub>3</sub>](NO<sub>3</sub>)<sub>3</sub>, [Zn(N<sub>2</sub>H<sub>4</sub>)<sub>3</sub>](NO<sub>3</sub>)<sub>2</sub>, and [Cd(N<sub>2</sub>H<sub>4</sub>)<sub>3</sub>](NO<sub>3</sub>)<sub>2</sub> [180]. All of these were tested by underwater detonation tests measuring shock-wave overpressure, shock-wave energy equivalent, and bubble energy equivalent and were further compared to typical explosives such as RDX, HMX, TNT, and PETN. Similar complex salts contain azide ion in addition to ethylenediamine as a ligand [181]. Examples are [Cu<sub>2</sub>(EN)<sub>2</sub>(N<sub>3</sub>)<sub>4</sub>] and [Co(EN)<sub>2</sub>(N<sub>3</sub>)<sub>2</sub>](NO<sub>3</sub>).

Five bis(ethylenediamine)metal perchlorate complexes such as  $[M(EN)_2](ClO_4)_2$  (where  $M = Mn, Co, Ni, Cu, Zn$ ) have been prepared and characterized by gravimetric methods, TGA, DTA, IR, and elemental analysis [182]. Thermal stability of the complexes was found to decrease in the following order:  $[Zn(EN)_2](ClO_4)_2 > [Mn(EN)_2](ClO_4)_2 > [Ni(EN)_2](ClO_4)_2 > [Cu(EN)_2](ClO_4)_2 > [Co(EN)_2](ClO_4)_2$ . Explosion-delay measurements were carried out to investigate the response of these complexes under conditions of rapid heating. If the logarithm of the explosion delay is plotted against the reciprocal absolute temperature, a straight line can be drawn through the data points.

## 8 C<sub>3</sub> and C<sub>4</sub> Di- and Triamines

### 8.1 Propylene Diamine

There exist two isomeric propylene diamines, 1,2-diaminopropane,  $H_3CCH(NH_2)CH_2NH_2$ , CAS RN [78-90-0], and 1,3-diaminopropane, bis-aminomethylmethane,  $H_2NCH_2CH_2CH_2NH_2$ , CAS RN [109-76-2], both with a gross formula of  $C_3H_{10}N_2$ . and a molar mass of 74.12 g/mol. Physical properties of diaminopropane isomers are summarized in Table 40.

**Table 40:** Physical properties of diaminopropane isomers.

|                             | 1,3-diaminopropane                | 1,2-diaminopropane            |
|-----------------------------|-----------------------------------|-------------------------------|
| Molecular mass              | 74.12 g/mol                       | 74.12 g/mol                   |
| Density                     | 0.888 g/cm <sup>3</sup>           | 0.870 g/cm <sup>3</sup>       |
| Melting point               | 261.15 K = -12 °C = 10.4 °F       | 236.0 K = -37.1 °C = -34.9 °F |
| Boiling point               | 413.2 K = 140.1 °C = 284.1 °F;    | 392.7 K = 119.6 °C = 247.2 °F |
| Vapor pressure              | <1.1 kPa or 11.5 mm Hg (at 20 °C) | 1.9 Pa (at 20 °C)             |
| Refractive index $n_D^{20}$ | 1.458                             | 1.446                         |

Viscosity data for 1,2-diaminopropane have been obtained in the temperature range of 238 to 323 K (-35 to +50 °C) using an Ubbelohde viscometer [41]. The results were compared with existing data, and all the data were fitted to the Fulcher (Tammann-Hesse) equation by the method of least squares. The significance of the values of  $T_0$  in this equation for these and other associated liquids was correlated to the molecular structure of this molecule. The viscosity data in Table 41 below can be expressed by a Fulcher-type equation

$$\log \eta = -1.0755 + 165.754/(T - 166.751)$$

where  $\eta$  is the viscosity in cPs and  $T$  is the temperature in kelvin. This equation is valid for the range from 238 to 323 K (–35 to +50 °C). The accuracy of the results from the equation is  $\pm 1.1\%$ . The viscosity calculated for 298 K is 1.54 cPs (compared to 1.57 cPs listed in the table).

**Table 41:** Viscosity and density of 1,2-diaminopropane.

| Temperature |     | Viscosity |       | Density | Temperature |    | Viscosity |        | Density |
|-------------|-----|-----------|-------|---------|-------------|----|-----------|--------|---------|
| K           | °C  | mPa s     | cPs   | g/mL    | K           | °C | mPa s     | cPs    | g/mL    |
| 238         | –35 | 16.47     | 16.47 | 0.9140  | 283         | 10 | 2.206     | 2.206  | 0.8690  |

Data source: [41]

Comparing the temperature dependence of the IR spectra of the condensed phase heated slowly ( $dT/dt = 50\text{ °C/min}$ ) and the fast thermolysis ( $dT/dt > 100\text{ °C/s}$ ) of propylene-1,3-diammonium dinitrate (PDDN) and diperchlorate (PDDP), it was found that PDDP exploded on heating whereas PDDN decomposed with much less energy [183].  $\text{HNO}_3(\text{G})$  was formed by dissociation in the initial decomposition of PDDN, but no  $\text{HClO}_4(\text{G})$  was detected from PDDP. The X-ray density of PDDP is  $1.789\text{ g/cm}^3$ .

## 8.2 Diethylenetriamine

Diethylenetriamine, also known as 2,2'-iminodi(ethylamine),  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHCH}_2\text{CH}_2\text{NH}_2$ ,  $\text{C}_4\text{H}_{13}\text{N}_3$ , CAS RN [111-40-0], sometimes abbreviated DETA, is a trifunctional, high-boiling amine. It is often used as an intermediate in the chemical industry for the production of detergents, moisturizers, solvents, dyes, and ion exchangers. DETA is a by-product of the production of ethylenediamine from ethylene dichloride. It can be produced by reaction of 1,2-dichloroethane with ammonia, but this reaction also generates ethylene diamine, piperazine, and  $\beta$ -aminoethyl-*N*-piperazine as by-products, some of which remain in DETA as contaminants. Commercial DETA may contain up to 9% of contaminants, thus affecting the properties of fuel mixtures prepared using this type of DETA. DETA was first used as a rocket fuel in the mixture with UDMH in the propellant called Hydryne (MAF-4) and in the mixed amine fuels MAF-1, MAF-3, and MAF-5.

### 8.2.1 Physical Properties of Diethylenetriamine

The physical properties of diethylenetriamine are summarized in Table 42.

**Table 42:** Physical properties of diethylenetriamine.

| Property                    | SI units                                                             | Non-SI units                                                                                             | References |
|-----------------------------|----------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------|------------|
| Molecular mass              | 103.17 g/mol                                                         | 9.693 mol/kg                                                                                             |            |

The *USAF Propellant Handbooks, Hydrazine Fuels, Volume 1*, contains a unit with physical properties of DETA from which the following properties were copied [184]. It also has three graphs showing the density, vapor pressure, and viscosity of DETA as a function of temperature. The density of DETA as a function of temperature for the range 273–333 K (0–60 °C) can be calculated using the equation

$$\rho = 1.1955 - 8.2751 \times 10^{-4} T$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin. The vapor pressure of DETA for the range 293 to 483 K (20 to 210 °C) can be calculated using the equation

$$\log P = 8.3982 - 2651.50/T$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The absolute viscosity of DETA as a function of temperature for the range 253 to 303 K (−20 to +30 °C) can be calculated using the equation

$$\log \mu = 18.3037 - 1.1384 \times \frac{10^4}{T} + 1.833 \times \frac{10^6}{T^2}$$

where  $\mu$  is the absolute viscosity in cPs and  $T$  is the temperature in kelvin. No reliable data on enthalpy of formation of DETA could be found, but the best available data is  $\Delta H_f^{298} = -77.4 \text{ kJ/mol} = -18.5 \text{ kcal/mol}$ .

### 8.2.2 Chemical Properties of Diethylenetriamine

When exposed to air, DETA slowly auto-oxidizes and discolors brown. Commercial DETA may contain 9–10 mass-% of other amines as contaminants. The main contaminant is 2-aminoethylpiperazine.

For U.S. government procurement, the purity requirements of DETA were at one time defined by MIL-D-50025B(MU), which was later superseded by Federal Specification O-D-1271 dated November 1967 (20 June 1985), which was canceled in 1998 and superseded by A-A-59162, which was renewed in 2015. These specifications contain descriptions of analysis methods for quality control of this fuel, which is also used as a decontaminating agent. Like ethylenediamine, DETA can also be used to sensitize nitromethane, making a liquid explosive compound similar to PLX.

### 8.2.3 Fuel Mixtures Containing Diethylenetriamine

There have been several fuel mixtures that contained diethylenetriamine, but none is still in use as a rocket fuel. The description given here is mostly a historical account. There is some duplication of the information on MAF fuel mixtures between the current section and the UDMH fuel blends section in this volume in the chapter “Dimethylhydrazines.”

### 8.2.4 Hydyne

Hydyne was a mixture of 60 mass-% UDMH and 40 mass-% DETA. It has also been designated as MAF-40 (mixed amine fuel) or MAF-4. It was first used as fuel in a Jupiter-C satellite launcher, which successfully launched the first U.S. artificial satellite, Explorer-1. Jupiter-C was originally designed for ethanol, but the substitution with the denser Hydyne in the same given tank envelope gave it a higher performance. In a Redstone ballistic missile, the substitution of ethanol with Hydyne would have increased its range by 12%. The performance of MAF-4 can be further increased by adding up to 9 mass-% acetonitrile to the fuel mix.

#### 8.2.4.1 Physical Properties of Hydyne

The physical properties of Hydyne are summarized in Table 43.

The *USAF Propellant Handbooks, Hydrazine Fuels, Volume 1* contains a unit with physical properties of MAF-4 from which the following properties were copied [184]. It also has three graphs showing the density, viscosity, and vapor pressure of MAF-4 as

**Table 43:** Physical properties of Hydyne.

| Property             | SI units                               | Other units                                |
|----------------------|----------------------------------------|--------------------------------------------|
| Freezing point       | <189 K                                 | <-84.4 °C                                  |
| Boiling point        | 343 K                                  | 69.6 °C                                    |
| Density              | 0.859 g/cm <sup>3</sup> (at 20 °C)     | 0.809 g/cm <sup>3</sup> (at 71 °C)         |
| Vapor pressure       | 0.18 atm (at 20 °C)                    | 1.23 atm (at 71 °C)                        |
| Viscosity            | 1.24 cPs (at 20 °C)                    | 0.514 cPs (at 71 °C)                       |
| Critical temperature | 559 K                                  | 286 °C                                     |
| Heat capacity cp     | 2.71 J g <sup>-1</sup> K <sup>-1</sup> | 0.648 cal g <sup>-1</sup> °C <sup>-1</sup> |

Data source: [184]

a function of temperature. The density of MAF-4 as a function of temperature for the range 223 to 343 K (-50 to +70 °C) can be calculated using the equation

$$\rho = 1.1697 - 1.086 \times 10^{-3} T$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin. The vapor pressure of MAF-4 for the range 290 to 350 K (17 to 77 °C) can be calculated using the equation

$$\log P = 8.2762 - 1849.4/T$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin. The approximate absolute viscosity of MAF-4 can be calculated from the equation

$$\log \mu = -13.063 + 1.1095 \times \frac{10^4}{T} - 3.2894 \times \frac{10^6}{T^2} + 3.4457 \times \frac{10^8}{T^3}$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. Assuming an average molecular mass of 72.1498 g/mol for the mixture, and assuming additive behavior and no heat of mixing of the two fluids, the average enthalpy of formation of MAF-4 would be +15.533 kJ/mol = +3.7125 kcal/mol or +51.455 cal/g.

#### 8.2.4.2 Chemical Properties of Hydyne

The chemical properties of Hydyne are determined by those of its constituents. Hydyne is hygroscopic and absorbs moisture and carbon dioxide from the air. Hydyne is miscible with water in all proportions but is immiscible with gasoline.

The analysis of Hydyne mixtures can be performed by measuring physical properties that are quite different for the two constituents, such as index of refraction or dielectric constant, and comparing the results to data from a calibration curve. This method is suitable only for binary mixtures and will fail if the propellant contains a third ingredient (e.g., acetonitrile).

Mixtures of hydrazine or UDMH with DETA can be analyzed by an acidimetric method in which a sample is taken and titrated before and after reaction with sali-

cyl aldehyde. Salicyl aldehyde ties up the hydrazine(s) as hydrazone(s), which have a different pK than the free hydrazine(s) or DETA [185].

The water content of Hydyne can be determined by gas chromatography (GC) or IR spectrophotometry [186].

The radiolysis of Hydyne, UDMH, and DETA was studied in preparation for future space use or potential radiation exposure in a nuclear war battlefield [187]. The gas evolution of UDMH, DETA, and Hydyne when exposed to  $8.5 \times 10^6$  rads was 199, 101, and 164 cm<sup>3</sup>, respectively. It was discovered that the undesirable gas evolution can be reduced by the addition of 5% of a radical scavenger, such as methyl methacrylate.

#### 8.2.4.3 Handling of Hydyne

The vapor pressure of Hydyne is governed by the vapor pressure of UDMH; consequently, the handling precautions are the same as for handling UDMH under pressure and in large quantities.

As always, good ventilation of the work area where Hydyne is transferred or stored is important. Storage tanks should have a pad of nitrogen under slightly positive pressure to prevent the intrusion of air and carbon dioxide.

Yellow discoloration may indicate that some air has intruded or was not carefully excluded when the storage tanks were filled. Hydyne can be stored for very long times. Therefore, it is also suitable for missiles with prepackaged and exchangeable propellant tanks [188]. Hydyne is non-detonable. It is insensitive to initiation by booster charges consisting of 50–100 g tetryl [189].

The flammable limits of Hydyne vapors in air are similar to those of UDMH (based on measurements by the USBM): At 788 kPa and 373 K (7.8 atm and 100 °C), the lower limit of flammability is at  $4.2 \pm 0.2$  vol-% Hydyne, and that of UDMH under identical conditions is  $2.2 \pm 0.3$  vol-%. It was difficult to determine the upper limit of flammability because at 373 K and in the presence of air, the incipient oxidation reaction and decomposition resulted in a substantial pressure increase (twice the starting pressure) before the mixture could be ignited.

This troublesome decomposition reaction had also been observed in other laboratories [190]. Hydyne vapors will auto-ignite in inert gases (helium or nitrogen) in the absence of oxygen at 671 K (398 °C). In air, the vapors will ignite at 514 K (241 °C). For pure UDMH, the corresponding values are 656 K (383 °C) and 507 K (234 °C), respectively.

Hydyne fires can be fought and extinguished with water, similar to UDMH fires. Open-pan fires of Hydyne were studied to find optimum and safe fire-extinguishing methods [191]. It was noted that fuel-rich flames emitted large quantities of hydrogen cyanide, which might be dangerous to firefighters if they inhale it. The Hydyne used in these tests consisted of 41% UDMH, 50% DETA, and 9% acetonitrile.

### 8.2.5 Mixed Amine Fuel MAF-1

Mixed amine fuel 1, MAF-1, is a mixture of a hydrazine and an amine with a nitrile compound that adds energy in the form of the  $\text{—C}\equiv\text{N}$  cyanide group. MAF-1 is a clear, yellowish liquid with a fishy odor. It is hygroscopic and will absorb carbon dioxide; therefore, air exposure must be kept at a minimum. MAF-1 was used as the fuel for inhibited red fuming nitric acid (IRFNA) in the ASM-N7A and Bullpup B (GAM-83) air-to-ground missiles, which were placed in service for the U.S. Air Force and U.S. Navy by the thousands (ASM-N-7 1959-1970s; ASM-N-7A/AGM-12B 1965-1970s). The AGM-12 Bullpup was the first mass-produced air-to-ground joystick-radio-guided missile in the U.S. military. Deployed by the U.S. Navy in 1959, it was created based on defensive needs in the Korean War. The Bullpup was used on aircraft such as the A-4 Skyhawk, A-6 Intruder, F-105 Thunderbolt, and F-4 Phantom. It was eventually replaced in the 1970s by the AGM-62 Walleye and the AGM-65 Maverick. When the Bullpup missiles were decommissioned, large amounts of MAF-1 had to be neutralized and disposed of.

#### 8.2.5.1 Physical Properties of Mixed Amine Fuel MAF-1

The *USAF Propellant Handbooks, Hydrazine Fuels, Volume 1* contains a unit with physical properties of MAF-1, from which the following properties were copied [184]. It also has two graphs showing the density and vapor pressure of MAF-1 as a function of temperature. The density of MAF-1 as a function of temperature for the range 223 to 344 K ( $-50$  to  $+71^\circ\text{C}$ ) can be calculated using the equation

$$\rho = 1.1391 - 9.0228 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. The density range at 298 K as specified by MIL-P-23741A is  $0.863\text{--}0.875 \text{ g/cm}^3$ . The vapor pressure of MAF-1 for the range 273 to 397 K ( $0$  to  $124^\circ\text{C}$ ) can be calculated using the equation

$$\log P = 12.9134 - 5008.6/T + 5.2332 \times \frac{10^5}{T^2}$$

where  $P$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

#### 8.2.5.2 Chemical Properties of Mixed Amine Fuel MAF-1

The composition of MAF-1 is defined by military specification MIL-P-23741A (canceled) is shown in Table 44 [192]. In addition to the composition called out in the military specification, Thiokol RMD also formulated a propellant blend that appeared to be at one boundary of the specification tolerance range.

The deviations may be partially due to the poor quality of commercial DETA, which may contain up to 10 mass-% of other amines as contaminants.

**Table 44:** Composition of mixed amine fuel MAF-1.

| Constituent        | MIL-P-23741A<br>Composition, mass-% | Thiokol RMD<br>Nominal composition, mass-% |
|--------------------|-------------------------------------|--------------------------------------------|
| DETA               | 49.7 ± 0.7                          | 50.5                                       |
| UDMH               | 39.0 ± 1.5                          | 40.5                                       |
| CH <sub>3</sub> CN | 10.0 ± 1.0                          | 9.0                                        |
| H <sub>2</sub> O   | 1.0 maximum                         | —                                          |

### Analysis of Mixed Amine Fuel MAF-1

Analytical methods for the analysis of MAF-1 are described in MIL-P-23741A. The UDMH content of MAF-1 can be determined by iodometric titration in HCl solution. The acetonitrile content of MAF-1 is determined by an IR spectrophotometric method between 4 and 5  $\mu\text{m}$  or by gas chromatography. The water content can be determined by gas chromatography.

#### 8.2.5.3 Materials Compatibility with MAF-1

Real-time storage data based on long periods of exposure of Bullpup 2014-T6 aluminum alloy tankage revealed that containment of MAF-1 fuel and IRFNA oxidizer by 2014-T6 aluminum alloy tankage for more than 3 years had not affected the mechanical, physical, or chemical properties of the materials to a degree that would impede tactical performance of the missile [193].

The compatibility of Bullpup missile tankage and components with IRFNA and MAF-1 propellants was measured for a period of 10–12 years [194]. Tankage material was the 2014-T6 aluminum alloy. Evaluation of the tank and component surfaces disclosed only minor corrosion effects of a general surface nature. The degree of material degradation that occurred was considered insignificant and would not alter the functional capability of the missile.

#### 8.2.5.4 Toxicity of MAF-1

Inhalation and cutaneous toxicity studies of MAF-1 were initiated to determine the toxicity of the fuel and compare it with those of the separate components [195]. The toxicity of MAF-1 is dominated by the vapor pressure of UDMH.

### 8.2.6 Mixed Amine Fuel MAF-3

MAF-3 was a mixture of 80% DETA and 20% UDMH and was once used in a Sparrow III missile with prepackaged propellants. Properties of MAF-3 were once specified by MIL-P-23686A, Propellant, mixed amine fuel, MAF-3. The density of MAF-3 can be calculated from the equation

$$\rho = 1.1709 - 8.5269 \times 10^{-4} T$$

where  $\rho$  is the density in  $\text{g/cm}^3$  and  $T$  is the temperature in kelvin. The approximate absolute viscosity of MAF-3 can be calculated from the equation

$$\log \mu = -3.3444 + 2828.6/T - 1.0403 \times \frac{10^6}{T^2} + 1.6141 \times \frac{10^8}{T^3}$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin. The properties of MAF-4 are described under the previous heading "Hydyne."

### 8.2.7 Mixed Amine Fuel MAF-5

There was never an official composition for the blend called MAF-5, but rudimentary information gathered from Thiokol RMD reports indicated that the approximate composition of this fuel mixture was 50.5% DETA, 29.5% UDMH, and 20% acetonitrile. The acetonitrile content was thus substantially higher than in MAF-1 [184].

### 8.2.8 Diethylenetriammonium Salts

Diethylenetriammonium(3+) trinitrate forms a 1 : 1 addition compound with AN, which also eliminates the III  $\leftrightarrow$  IV phase transition of AN. Diethylenetriamine nitrates form complexes with metal nitrates similar to those formed with propane-1,3-diamine and its nitrates [196].

Diethylenetriammonium(3+) trinitrate (DETN) forms a eutectic with EDDN, melting between 460.7 and 461.3 K (187.6 and 188.2°C) when it was being tested as a melt-cast explosive and as a replacement for Composition B in mortar rounds and bomb fills [164]. The preparation of DETN is a simple acid–base reaction:

### 8.3 $\text{C}_{n>2}$ Polyalkylammonium Salts

Similar to ethylenediamine, 1,3-propanediamine (bis-aminomethylmethane) forms salts with most strong acids. 1,3-propanediamine forms a diperchlorate salt with perchloric acid, with an excess of acid.

#### 8.3.1 1,3-Propanediammonium Diperchlorate

Propane-1,3-diammonium diperchlorate,  $[\text{H}_3\text{N}^+\text{CH}_2\text{CH}_2\text{CH}_2\text{N}^+\text{H}_3](\text{ClO}_4^-)_2$ ,  $\text{C}_3\text{H}_{12}\text{Cl}_2\text{N}_2\text{O}_8$ , PDDP, is an energetic salt with a molecular mass of 275.04 g/mol and mon-

oclinic crystals crystallizing in space group  $P2_1/c$  with the unit cell parameters of  $a = 7.298(4) \text{ \AA}$ ,  $b = 14.388(9) \text{ \AA}$ ,  $c = 9.708(6) \text{ \AA}$ ,  $\beta = 96.79(4)^\circ$ ,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.8 \text{ g/cm}^3$  [197].

A comparison of the temperature dependence of the IR spectra of the condensed phase with slow heating ( $dT/dt = 5^\circ\text{C/min}$ ) and the fast thermolysis ( $dT/dt \geq 100^\circ\text{C/s}$ ) of propane-1,3-diammonium dinitrate (PDDN) and diperchlorate (PDDP) showed that PDDP exploded on heating, whereas PDDN decomposed with much less energy [198].  $\text{HNO}_3(\text{G})$  was formed by dissociation in the initial decomposition of PDDN, but  $\text{HClO}_4(\text{G})$  was not detected from PDDP decomposition. PDDP is unique among the compounds studied by this technique in that a solid–solid phase transition could be detected during rapid heating prior to the onset of decomposition. The initial crystal structure of PDDP was characterized by XRD: as monoclinic, space group  $P2_1/c$ , and lattice parameters of  $a = 7.316(2) \text{ \AA}$ ,  $b = 14.428(2) \text{ \AA}$ ,  $c = 9.742(2) \text{ \AA}$ ,  $\beta = 96.81^\circ$ ,  $V = 1021.1(3) \text{ \AA}^3$ ,  $Z = 4$ , and  $\rho_{\text{XRD}} = 1.789 \text{ g/cm}^3$ .

Bis(propylenediamino) metal perchlorate complexes such as  $[\text{M}(\text{PN})_2](\text{ClO}_4)_2$  (where  $\text{M} = \text{Cr, Mn, Ni, Cu, Zn}$  and  $\text{PN} = \text{propylenediamine}$ ) have been prepared and characterized by gravimetric methods, TGA, DTA, IR, and elemental analysis [199]. The thermal stability of the complexes decreased in the following order:  $[\text{Cr}(\text{PN})_2](\text{ClO}_4)_2 > [\text{Mn}(\text{PN})_2](\text{ClO}_4)_2 > [\text{Zn}(\text{PN})_2](\text{ClO}_4)_2 > [\text{Ni}(\text{PN})_2](\text{ClO}_4)_2 > [\text{Cu}(\text{PN})_2](\text{ClO}_4)_2$ . Similar complexes were formed with bis(diethylenetriamine) metal nitrates.

3-amino-1-propylammonium perchlorate,  $[\text{C}_3\text{H}_{11}\text{N}_2]\text{ClO}_4$ , forms crystals with a molecular mass of  $M = 174.58 \text{ g/mol}$ , which are held together by an extensive hydrogen-bonded system [200]. It forms orthorhombic crystals at  $T = 296 \text{ K}$  in space group  $Pbca$  and cell parameters of  $a = 12.337(4) \text{ \AA}$ ,  $b = 12.888(6) \text{ \AA}$ ,  $c = 9.677(7) \text{ \AA}$ ,  $V = 1538 \text{ \AA}^3$ ,  $Z = 8$ , and  $\rho = 1.507 \text{ g/cm}^3$ .

### 8.3.2 1,3-Propanediammonium Dinitrate and Diperchlorate

1,3-propanediammonium dinitrate  $[\text{PDDN}, \text{NO}_3\text{NH}_3(\text{CH}_2)_3\text{NH}_3\text{NO}_3]$  is a potential explosive but does not have the same thermal stability as EDDN. PDDN undergoes a solid–solid phase transition at  $335 \text{ K}$  ( $62^\circ\text{C}$ ) and melts at  $399 \text{ K}$  ( $126^\circ\text{C}$ ) without decomposition [201]. Evolution of  $\text{HNO}_3$  vapor occurs at  $553 \text{ K}$  ( $280^\circ\text{C}$ ), followed by the oxidation–reduction products of  $\text{HNO}_3$  and the alkylamine. 1,3-propanediammonium diperchlorate, PDDP,  $\text{ClO}_4\text{NH}_3(\text{CH}_2)_3\text{NH}_3\text{ClO}_4$ , is a potential explosive. PDDP undergoes a solid–solid phase transition at  $423 \text{ K}$  ( $150^\circ\text{C}$ ), which significantly changes the crystal lattice structure and the ion dynamics. The decomposition starts soon after melting at  $553 \text{ K}$  ( $280^\circ\text{C}$ ) and leads to  $\text{HCl}$ ,  $\text{CO}$ ,  $\text{CO}_2$ , and  $\text{H}_2\text{O}$  as products. 1,3-propanediammonium diperchlorate forms crystals with strong hydrogen bonding [202].

### 8.3.3 1,4-Butanediammonium Dinitrate

The effects of single or double protonation of 1, $\omega$ -alkylenediamines and of substitution along the carbon chain by methyl or fluorine groups on the molecular structure (bond lengths and bond orders) were calculated by an *ab initio* self-consistent field molecular orbital procedure using the GAUSSIAN 82 system of programs [203]. The emphasis was on 1,4-diaminobutane and its derivatives and protonated forms since these compounds have mostly been investigated using experimental methods. It was found that the protonation of a nitrogen causes its bond to the terminal carbon of the chain to become considerably weaker. The weakening is even more pronounced when the terminal carbon is methylated.

#### 8.3.3.1 Thermal Stability of 1,4-Butanediammonium Dinitrate

The kinetic deuterium isotope effect for the induction period during the decomposition of 1,4-butanediammonium dinitrate in a differential scanning calorimeter was determined at 538, 543, and 548 K (265, 270, and 275 °C) for both normal 1,4-butanediammonium dinitrate (BDD) and hexadeutero-1,4-butanediammonium dinitrate (BDD-d6) in which the hydrogen atoms on the nitrogen atoms had been replaced by deuterium atoms [204]. The  $k_H/k_D$  ratio was found to be 1.09, 1.11, and 1.33 at 538, 543, and 548 K (265, 270, and 275 °C), respectively. The faster rate for the protium compound can be interpreted as indicating C—N bond breaking in the rate-determining step. The corresponding activation energies were 288 and 241 kJ/mol (68.9 and 57.5 kcal/mol) for BDD and BDD-d6, respectively.

The thermal decomposition of 1,4-butanediammonium dinitrate (BDDN) was investigated using DSC, ARC, TGA, tandem GC/MS, and high-performance liquid chromatography (HPLC) [205, 206]. BDDN decomposes to a mixture of condensable and gaseous products. The composition of the products suggests that early in the sequence of reactions, a proton transfer takes place from a cation to an anion, followed by a C—N bond rupture. Heterocyclic decomposition products form by a cyclo-elimination process. This reminds one of the fact that 1,5-pentanediammonium dinitrate cannot be prepared at all because of its tendency to form piperidine derivatives. Nitramine and nitrosamine compounds may also play a role as intermediates in the BDDN decomposition. Isotope substitution with deuterium had a measurable effect on thermal stability and sensitivity and gave some clues about the key steps in BDDN decomposition [207].

Mass spectrometric investigation of the initial stages of the decomposition of BDDN using a molecular beam-sampling time-of-flight quadrupole mass spectrometer system showed that the initial step is the dissociation into 1,4-butanediamine and nitric acid [208]. Standard electron impact ionization and fast atom-bombardment mass spectrometric analyses of BDDN gave support to the molecular beam study. See also [21, 154].

### 8.3.4 1,4-Butanediammonium Diperchlorate

The strand-burning rate of 1,4-butanediammonium diperchlorate (also called tetramethylenediamine diperchlorate or tetramethylenediammonium diperchlorate) has been compared to that of ethylenediammonium diperchlorate and phenylenediammonium diperchlorate [169]. The burning-rate function of tetramethylenediammonium diperchlorate differs substantially from those of ethylenediammonium diperchlorate and phenylenediammonium diperchlorate. In the range of 121-atm, the rate increased according to the function

$$r_b = 0.24p^{0.7}$$

where  $r_b$  is the burning rate in cm/s and  $p$  is the pressure in atmospheres. Above 21 atm the curve slope increased somewhat, but at 37 atm the rate of combustion dropped abruptly from 4.2 to 1.0–1.3 cm/s; furthermore, it dropped so rapidly that it was impossible to obtain an intermediate rate value. In the range from 48 to 200 atm, the combustion did not propagate.

### 8.3.5 1,6-Hexanediammonium Dinitrate

Mass spectrometric investigations [205, 208], on the initial stages of thermal decomposition of 1,6-hexanediammonium dinitrate, hexamethylenediamine dinitrate, HDDN, CAS RN [6143-53-9], revealed the formation of the corresponding amine and nitric acid at 433 to 453 K (160 to 180 °C). The nitric acid partially decomposed to produce nitrogen dioxide.

The heat of combustion at constant volume of hexamethylenediamine dinitrate is 4177 kJ/mol = 998.4 kcal/mol [60].

### 8.3.6 Pentaerythritylammonium Salts

Pentaerythritol is the polyol that when nitrated forms the frequently used primary explosive PETN. Replacing all hydroxyls with amino groups leads to pentaerythritylamine, pentaerythrityltetramine,  $C(CH_2NH_2)_4$ , 2,2-bis-aminomethyl-1,3-propanediamine, a strong amine that forms energetic salts with nitric acid, perchloric acid, or trinitromethane. It can form mono-, di-, tri-, or tetranitrates or -perchlorates.

Pentaerythrityltetramine can be prepared by treating pentaerythrityl tetrachloride with excess hot, highly compressed ammonia in 57% yield at 52% conversion. The ammonolysis may be conducted either in supercritical ammonia alone or in methanol as the solvent. The product amine is isolated by precipitating it as the water-insoluble disulfate; simply washing the precipitate with water yields disulfate of high purity [209].

Pentaerythrityltetramine was prepared by starting from pentaerythritol via two steps. Pentaerythrityl tetrabromide was then treated with sodium p-toluenesulfonamide to give an intermediate, which was converted to pentaerythrityl tetramine disulfate. The overall yield was 30% [210].

### 8.3.7 Pentaerythrityl Tetraammonium Tetranitrate and Pentaerythrityl Tetraammonium Tetraperchlorate

The tetraperchlorate of pentaerythrityltetramine, a very explosive substance, was prepared for the first time in a U.S. Navy laboratory [165]. The gross formula is  $C_5H_{20}N_4O_{16}Cl_4$ , CAS RN [89416-99-9].

When the solid crystalline sulfate of 2,2-bis(aminomethyl)-1,3-diaminopropane is treated with excess dilute nitric acid, the sulfate ion is completely displaced by nitrate ion in a metathetical reaction [211]. The resulting crystalline nitrate,  $C(CH_2NH_2)_4 \cdot 4HNO_3$ , is only slightly soluble in water and therefore can be easily isolated in high purity. Its identity was established by acid–base titration, proton magnetic resonance, IR spectrophotometry, and elemental analysis. It may be stored at 423 K (150 °C) for many hours with negligible decomposition, but it decomposes within a few minutes at 473 K (200 °C). Attempts to cause it to detonate have been unsuccessful. When ignited, the nitrate burned slowly, leaving a carbonaceous residue. The low solubility, high melting point, high density, and thermal stability of this nitrate are a sharp contrast to the properties of ammonium nitrate and methyl ammonium nitrate. Density of the crystals is 1.7 g/cm<sup>3</sup>, which is well above the density of ethylene diamine dinitrate (1.58 g/cm<sup>3</sup>), MEAN (1.42 g/cm<sup>3</sup>), and hexamethylene tetramine dinitrate (1.57 g/cm<sup>3</sup>) and about the same as that of AN (1.72 g/cm<sup>3</sup>).

Pentaerythrityl tetraammonium tetranitrate decomposes by initially liberating  $HNO_3$  before an oxidation reaction consumes the organic skeleton. Ammonia, AN,  $NO_2$ , and  $N_2O$  are by-products. The pyrolysis mechanism of pentaerythrityltetraammonium tetranitrate,  $[C(CH_2NH_3)_4](NO_3)_4$ , PTTN, was determined by rapid-scan FTIR spectroscopy [23]. The initial gaseous product at about 490 K was desorbed  $HNO_3$ , resulting, most likely, from the transfer of a proton from the cation to the anion. C–N bond fission also took place and liberated  $NH_3$ , which reacted with  $HNO_3(G)$  to produce  $NH_4NO_3(G)$ .  $HNO_3(G)$  was rapidly consumed, while oxidized fragments of the hydrocarbon portion appeared. The sequence of appearance of products suggests that decomposition of the cation begins at the exterior and progresses inward, a fact that is consistent with chemical attack by an external agent, such as  $HNO_3$ . PTTN is intriguing because its melting–decomposition point is higher than that of AN (~490 vs. 440 K), and it does not undergo the solid–solid phase transitions that AN suffers from. At slow heating rates in TGA, a five-step weight loss occurred in the 493–555 K range, the first four steps of which (493–505 K) each corresponded to the loss of one  $HNO_3$ . A study of the thermal decomposition mechanism of the corresponding perchlorate salt  $[C(CH_2NH_3)_4](ClO_4)_4$  was complicated by premature deflagration or detonation as soon as the temperature reached 520 K. The salt is excessively shock sensitive. The crystal structure of PTTN at 296 K is tetragonal, space group  $P4_1$  (or  $P4_3$ ), with crystal lattice parameters  $a = 10.156(2)$  Å and  $c = 14.629(4)$  Å.

Based on a detailed study of the electron density distribution function in pentaerythrityltetraammonium tetranitrate, reconstructed from high-resolution XRD data, the effect of unusual (from the standpoint of electrostatic considerations)

anion–anion contacts on the charge distribution in the crystal was analyzed [212]. Interactions between the likely charged species can cause a significant redistribution of the charge density over the anionic (cationic) sublattice and, as a result, significantly affect the strength of conventional cation–anion bonds.

## 9 Cycloaliphatic Amines

Cycloaliphatic amines are composed of a cyclic hydrocarbon structural component and an amine functional group external to that ring. The external amino group may also carry additional linear alkyl groups [213]. The family consists of primary amines directly bonded to a cycloalkane by a single bond to a secondary carbon and includes cyclopropylamine,  $C_3H_7N$ ; cyclobutylamine,  $C_4H_9N$ ; cyclopentylamine,  $C_5H_{11}N$ ; cyclohexylamine,  $C_6H_{13}N$ ; cycloheptylamine,  $C_7H_{15}N$ ; cyclooctylamine,  $C_8H_{17}N$ ; and cyclododecylamine,  $C_{12}H_{25}N$ . Up through  $C_8$  they are colorless liquids at room temperature. There are numerous cycloaliphatic diamines. Cycloaliphatic amines are strong bases with basicities similar to those of simpler primary, secondary, or tertiary amines. Common reactions are salt formation with Brønsted and Lewis acids and exhaustive alkylation to form quaternary ammonium cations. Before a U.S. Food and Drug Administration ban on 1 January 1970, cyclamate non-caloric sweeteners were the major derivatives driving cyclohexylamine production. The melting point of cyclohexylammonium nitrate,  $C_6H_{11}NH_3NO_3$ , is 431 K = 158 °C.

### 9.1 Cyclopropylamine

Numerous hydrocarbons have been synthesized in which the strain from a three-carbon ring adds to the heat of combustion and enthalpy of formation. The same strategy has been applied to produce amines with better rocket performance. The strained bonds in the cyclopropyl ring add energy to the molecule, and that might make it a better rocket fuel than normal propylamine. The standard enthalpy of combustion of liquid cyclopropylamine,  $\Delta H_{\text{comb}}$ , was found to be  $-(2227 \pm 0.4) \text{ kJ/mol} = -(532.20 \pm 0.10) \text{ kcal/mol}$  by oxygen-bomb combustion calorimetry [214]. The standard enthalpy of formation,  $\Delta H_o^f(298.15 \text{ K})$ , of the liquid is  $+(45.8 \pm 0.5) \text{ kJ/mol} = +(10.95 \pm 0.12) \text{ kcal/mol}$ . The enthalpy of vaporization was derived from vapor pressure measurements, and the standard enthalpy of formation in the ideal gaseous state was calculated. The data are summarized and compared to those of other cycloalkylamines in Table 45.

The IR ( $4000\text{--}150 \text{ cm}^{-1}$ ) and Raman ( $4000\text{--}50 \text{ cm}^{-1}$ ) spectra of gaseous, liquid, and solid cyclopropylamine have been recorded along with the IR spectrum of matrix-isolated samples [215]. The vibrational spectra of all phases were consistent with the

predominance of a conformer having the  $\text{—NH}_2$  group in a trans position to the ring C—C bond, in agreement with microwave spectra of this molecule [216].

Salts of the charge-delocalized cations of the triaminocyclopropenium (tac) family bearing alkylamino substituents have been prepared and shown to be air-stable and water-stable ionic liquids. The reaction of tetrachlorocyclopropene with secondary amines gives triaminocyclopropenium chloride, which can be combined with various anions (azide, dicyanomethanide, or dicyanohydroborate) to yield ionic liquids that have very short ignition delays with WFNA [217]. Secondary amines used in this study were diallylamine, diethylamine, and dipropylamine.

2-Azido-*N*-cyclopropylethanamine (CPAZ) and 2-azido-*N,N*-dimethylcyclopropanamine (ADMCPA) have been evaluated as a replacement for MMH in hypergolic bipropellant combinations [218, 219]. The enthalpy of formation of liquid CPAZ was predicted to be +382 kJ/mol (+91.2 kcal/mol), with a density of 0.993 g/cm<sup>3</sup>. The enthalpy of formation of liquid ADMCPA was predicted to be +402 kJ/mol (+96.2 kcal/mol).

**Table 45:** Properties of liquid cycloalkylamines.

| Property                                                       | Cyclopropylamine                               | Cyclobutylamine                                                                      | Cyclopentylamine                                                                     |

<sup>a</sup> Note: Values in parentheses were only estimated, not measured

Data source: [214,220]

## 9.2 Cyclobutylamine

The enthalpies of combustion of cyclobutylamine and cyclopentylamine were measured by precision oxygen-bomb combustion calorimetry [220]. The standard enthalpy of combustion,  $\Delta H_{\text{comb}}$  (298.15 K), of cyclobutylamine in the liquid state was 2866 ± 0.5 kJ/mol (684.96 ± 0.13 kcal/mol), and standard enthalpy of combustion of cyclopentylamine was 3444 ± 0.8 kJ/mol (823.25 ± 0.19). The enthalpies of formation

of three cycloalkylamines derived from heats of combustion are listed in Table 45 along with other physical properties.

### 9.3 Cubylamines

Cubylamines are the precursors for the synthesis of nitrocubanes. Cubylamines can be prepared from the corresponding carboxylic acids by a Curtius reaction. The CAS RN for cubylamine is [91424-46-3].

During an *ab initio* self-consistent-field molecular orbital study of the structures and relative bond strengths of some monoamine derivatives of cubane, azacubane, and 1,3-diazacubane, the focus was on the effect of the  $\text{NH}_2$  group on the strengths of the endocyclic strained bonds in these molecules and, in particular, on the conformation dependence of this effect [221]. The results showed a consistent bond weakening observed in one [and only one] C—C or C—N bond adjacent to the site of  $\text{NH}_2$  substitution. The particular bond that was weakened was in all cases essentially coplanar with the C— $\text{NH}_2$  bond and the position of the most negative electrostatic potential of the amine nitrogen. This direction-specific bond weakening was viewed as an example of an anomeric effect.

Polyamides with cubane as the backbone of a polymer chain would have high enthalpies of formation and high heats of combustion. Two monomer derivatives of cubane, cubane-1,4-dicarboxylic acid (CDA) and 1,4-diaminocubane (DAC), were used as building blocks. Polymers obtained by polymerizations of DAC, 1,6-hexamethylene diamine, and 1,4-diaminobenzene with cubane-1,4-dicarbonyl chloride, adipoyl chloride, and terephthaloyl chloride to obtain polyamides were characterized using FTIR,  $^1\text{H}$  NMR, and  $^{13}\text{C}$  NMR spectroscopy [222]. Thermal decomposition of the prepared polyamides by TGA and DSC showed a highly exothermic peak above 473 K (200 °C). Hydrolysis of polyamides containing DAC and detection of the hydrolysis product by ultraviolet (UV) spectroscopy showed that DAC was again released by the hydrolysis of the amide bonds in the polymer chain.

#### 9.3.1 Cubylammonium Nitrate and 1,4-Cubyl diammonium Dinitrate

The strain energy of the cubane alkyl rest gives this alkylammonium nitrate a substantially higher enthalpy of formation than a comparable octylammonium nitrate with a straight-chain or branched alkyl rest. Cubylammonium nitrate salts have potential applications as fuels in liquid gun propellants and as explosives by themselves. Although the cubyl compounds are water soluble, their solubility in aqueous HAN solutions is not large enough to permit preparation of viable liquid gun propellant mixtures. The cubane backbone stores above 669 kJ/mol (160 kcal/mol) of strain energy, making the ammonium nitrate salt derivatives considerably more energetic than the CNO atom balance suggests. Cubylammonium nitrate and cubane-1,4-diammonium

dinitrate (CUBDAN) have been investigated for their thermal stability. See also [223, 224].

The rapid thermal decomposition of cubylammonium nitrate and 1,4-cubyl-diammonium dinitrate was studied by analyzing the decomposition products with FTIR [225, 226]. The salts were rapidly decomposed ( $dT/dt$  faster than  $70^\circ\text{C/s}$ ), and the temperature profile and gas products as a function of pressure ( $6.8\text{--}1376\text{ kPa} = 1\text{--}200\text{ psi Ar}$ ) were measured. In this environment, the full strain energy of cubane is not released simultaneously with the redox reactions that involve the ammonium nitrate site because  $\text{C}_2\text{H}_4$  and/or  $\text{C}_2\text{H}_2$  are evolved. CUBDAN is the only alkyl-diammonium dinitrate salt that sublimes undecomposed during fast thermolysis. An estimated gas-phase basicity of about  $215\text{ kcal/mol}$  for the cubylamines is obtained from the tendency to release  $\text{HNO}_3(\text{G})$ . This value is surprising in light of the basicity values for other primary amines.

During the fast thermolysis of cubylammonium nitrate heated at a rate of  $90^\circ\text{C/s}$  under  $103\text{ kPa}$  ( $15\text{ psi}$ ) argon, no melting endotherm was detected either by DSC or in the thermal trace. During rapid heating, the decomposition exotherm appeared at  $423\text{--}448\text{ K}$  ( $150\text{--}175^\circ\text{C}$ ), depending on the pressure. By DSC, the exotherm began at about  $413\text{ K}$  ( $140^\circ\text{C}$ ). During the thermal decomposition of 1,4-cubyl-diammonium dinitrate when heated at an initial rate of about  $60^\circ\text{C/s}$  under  $7.5\text{ psi}$  argon, an exotherm occurred at about  $493\text{ K}$  ( $220^\circ\text{C}$ ) simultaneously with the appearance of gas decomposition products. In the differential scanning calorimeter, the decomposition occurred at  $448\text{--}473\text{ K}$  ( $175\text{--}200^\circ\text{C}$ ). No melting endotherm was found at low (DSC) or high heating rates. Extensive oxidation–reduction chemistry is indicated by the products, but the presence of a significant amount of  $\text{C}_2\text{H}_2$  showed that the strain energy of cubane was not released in one step under the conditions used. There were no larger hydrocarbon molecules in the gas phase. 1,4-cubyl-diammonium dinitrate was the only alkyl-diammonium dinitrate salt that was found to sublime during fast thermolysis.

*N,N*-diethanolammoniummethylcubane nitrate and 1,4-bis-(*N,N*-diethanolammoniummethyl)-cubane dinitrate have been patented as fuels in combination with HAN as liquid gun propellants [227]. The impetus of such mixtures was predicted to be higher than that of XM46.

### 9.3.2 Cubylammonium Dinitramide, 1,4-Cubyl diammonium Bis-dinitramide, and Bis-nitroformate

The crystal structure of 1,4-cubanediammonium bis(trinitromethanide)  $[\text{C}_8\text{H}_{12}\text{N}_2][\text{CN}_3\text{O}_6]_2$  was found to be monoclinic, space group  $C2/m$ , with the lattice parameters of  $a = 14.298(2) \text{ \AA}$ ,  $b = 8.408(1) \text{ \AA}$ ,  $c = 7.354(2) \text{ \AA}$ ,  $\beta = 103.42(2)^\circ$ ,  $V = 859.9(5) \text{ \AA}^3$ , and  $Z = 2$  and the X-ray density of  $\rho_{\text{XRD}} = 1.68 \text{ g/cm}^3$  [228]. The cubanediammonium cation and trinitromethanide anion have  $2/m$  and  $m$  crystallographic symmetries, respectively. The cation is linked to six trinitromethanide anions, three at each end, by a total of  $12\text{N}\cdots\text{H}\cdots\text{O}$  hydrogen bonds through the six cation H atoms. The cubane cage has a local threefold axis of symmetry along the long axis ( $\text{N1}\cdots\text{N1}$ ) of the cation and undergoes a large librational motion around this axis.

The crystal structures of cubane-1,4-diammonium dinitramide (**1**) and cubane-1,2,4,7-tetraammonium dinitramide (**2**) have been determined [229].

(**1**) crystallized in the space group  $P2_1/c$  with cell dimensions  $a = 6.018(2)$ ,  $b = 11.642(3)$ ,  $c = 9.754(3) \text{ \AA}$ , and  $\beta = 107.24(2)^\circ$ , while (**2**) crystallized in the space group  $P2_1/c$  with cell dimensions  $a = 9.401(4)$ ,  $b = 9.603(3)$ ,  $c = 12.603(4) \text{ \AA}$ , and  $\beta = 111.08(3)^\circ$ . In these structures, the ammonium substituents were symmetrically attached with respect to the cubane skeleton and had neither low-lying empty orbitals nor available lone pairs of electrons. Thus, they had a minimal effect on the symmetrical parameters of the cubane skeleton. All C—C bond lengths were close to the overall average C—C bond length for all reported cubanes of  $1.559 \text{ \AA}$ . The conformations

adopted by the dinitramide ions in both structures were quite different, with the bend, twist, and torsion angles for the dinitramide ion in **(1)** being significantly larger than those found for the dinitramide ions in **(2)**, due to the different types of hydrogen bonding found in the two structures. In **(2)**, the conformation adopted by the adjacent ammonium ions allowed two of the three protons from each ammonium cation to form hydrogen bonds in such a manner that they span either the *syn* or the *anti* oxygen atoms of a single dinitramide anion. The dinitramide anion is thus constrained by these interactions and is less free to twist and bend.

#### 9.4 Adamantylamine

Adamantane, tricyclo[3.3.1.1<sup>3,7</sup>]decane, C<sub>10</sub>H<sub>16</sub>, is difficult to obtain, and the expense of preparing its derivatives, such as adamantylamine and nitroadamantane, may prohibit future use of these chemicals as rocket propellants. A few adamantane derivatives have found practical applications as drugs, polymeric materials, and thermally stable lubricants. Nevertheless, these compounds have been prepared and characterized just in case they offer exceptionally high performance and just in case a more economical method of synthesis can be found.

The structure of 1-adamantanylammonium trinitromethide, was examined using XRD [230]. 1-adamantanylammonium trinitromethide, C<sub>11</sub>H<sub>18</sub>N<sub>4</sub>O<sub>6</sub>, *M* = 302.3, crystallized in orthorhombic crystals with the space group *Pnma* and crystal lattice parameters of *a* = 23.802(9) Å, *b* = 8.431(3) Å, *c* = 7.166(2) Å, *V* = 1438.0(8) Å<sup>3</sup>, *Z* = 4, *ρ*(flotational) = 1.37 g/cm<sup>3</sup>, *ρ*<sub>XRD</sub> = 1.396 g/cm<sup>3</sup>, and melting point 464 K = 191 °C. Both the adamantanylammonium cation and trinitromethide anion have mirror symmetry.

The crystal structure of tetraammonium adamantyl tetranitrate was determined using 3D single-crystal XRD [231]. The tetragonal structure has unit cell dimensions *a* = *b* = 10.046(1) Å and *c* = 8.980(2) Å. The X-ray density is 1.643 g/cm<sup>3</sup>.

## 10 Other Open-Chain Aliphatic Amines with More than One Nitrogen Atom in the Molecule

### 10.1 Primary Aliphatic Amines with More than One Nitrogen Atom in the Molecule

Ethylene diamine was already discussed in a section dedicated to this amine because it has found more applications than any of the other amines in this group, not only as free amine, but also in the form of its dinitrate salt.

A systematic examination of the thermal stability of a series of  $\omega$ -diaminoalkanes and their dinitrate salts  $\text{NO}_3\text{NH}_3(\text{CH}_2)_n\text{NH}_3\text{NO}_3$  for  $n = 2$  through  $n = 4$  and  $n = 6$  by rapid-scan FTIR showed that all of the salts liberate  $\text{HNO}_3$  and  $\text{NH}_3$  early in the first stage [232]. When  $n = 1 - 3$ , small-molecule products from redox reactions occurred in the second stage of decomposition. When  $n = 4, 6$ , the second stage involved cycloelimination to form pyrrolidine ( $n = 4$ ) and -ethylpyrrolidine ( $n = 6$ ). The temperature of the onset of exotherm was lower when  $n = 1$  than when  $n$  was larger. Intramolecular and intermolecular hydrogen bonding may play a significant role in these decomposition patterns. The reaction of  $\text{HNO}_3$  with  $\text{NH}_3$  in the gas phase produces  $\text{NH}_4\text{NO}_3$  aerosols at about 583 K (310 °C). The reduction of  $\text{HNO}_3$  or  $\text{NO}_2$  to NO and the oxidation of hydrocarbon residues to CO or  $\text{CO}_2$  occurs only above 603 K (330 °C).

The melting points and oxygen balances of nitrates of multifunctional aliphatic amines are summarized in Table 46.

### 10.2 Secondary Aliphatic Amines with More than One Nitrogen Atom in the Molecule

This section contains information on open-chain and saturated heterocyclic amines in which at least one of the nitrogens is linked with two carbon atoms on either side. A solid, melt-castable rocket propellant containing tetraethylenepentamine pentanitrate by itself or in mixtures with AN or AP can achieve specific impulses between 215 and 246 s [233].

The polymerization of ethyleneimine or propyleneimine results in the formation of polyethyleneimines or polypropyleneimine with many secondary  $-\text{NH}-$  groups and maybe two terminal  $-\text{NH}_2$  groups. The thermal stability of the perchlorate salt of this polymeric amine was measured using DTA, TGA, and isothermal weight loss as part of an evaluation as propellant ingredients [35, 234]. The thermal sensitivity of the salts increased with molecular weight.

**Table 46:** Melting points and oxygen balance (OB) of nitrates of multifunctional aliphatic amines.

| Compound name                                      | Acronym  | Molecular formula | OB    | Melt-<br>ing point |     |

## 11 Cycloaliphatic Secondary Aliphatic Amines with More than One Nitrogen Atom in the Molecule

The most stable bifunctional cycloaliphatic amine in this category is piperazine

Piperazine

It can form mononitrate and dinitrate (PIPDN) salts. The thermal decomposition of piperazinium(2+) dinitrate was examined using DSC and rapid-scan FTIR [162]. PIPDN initially yields  $\text{HNO}_3$ , but then generates a significant amount of *N,N*-dinitrosopiperazine along with small molecule fragments. The presence of nitrosamines strongly increases the health hazard of the materials upon heating. No nitramines were detected as thermolysis products. The crystal structure of PIPDN was determined during the same effort.

## 12 Tertiary Aliphatic Amines with More than One Nitrogen Atom in the Molecule

In an effort to find a less toxic replacement for MMH, the U.S. Army started looking for saturated tertiary multiamines and ethanamine azides. Saturated tertiary multiamines are compounds whose molecules have more than one amine nitrogen; those nitrogens are bonded to methyl ( $-\text{CH}_3$ ) and methylene ( $-\text{CH}_2-$ ) or ethylene ( $-\text{CH}_2-\text{CH}_2-$ ) groups (only), and there are no multiple-order bonds in those molecules. An investigation of the linear aliphatic amines was extended to include alicyclic tertiary amines, and the theoretical heats of formation were calculated [218, 235]. Aliphatic saturated tertiary multiamines tend to have shorter ignition delays (with IRFNA) than amine azides or tertiary monoamines. The cyclic amines did not show any advantages over the linear amines when ignition delays were tested with IRFNA, and density-specific impulses were calculated. Candidate tertiary amines under consideration included very symmetrical molecules such as tetrakis(dimethylamino)methane and 1,3,5-trimethylhexahydro-1,3,5-triazine.

### 12.1 *N,N,N',N'*-Tetramethyl-1,2-diaminoethane

*N,N,N',N'*-tetramethyl-1,2-diaminoethane, also known as *N,N,N',N'*-tetramethylethane-1,2-diamine, *N,N,N',N'*-tetramethylethanediamine; 1,2-ethanediamine, *N,N,N',N'*-tetramethyl-; 1,2-bis(dimethylamino)ethane, TMEDA,  $(\text{H}_3\text{C})_2\text{NCH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$ ,  $\text{C}_6\text{H}_{10}\text{N}_2$ , CAS RN [110-18-9], has been evaluated as a replacement for MMH in hypergolic bipropellant combinations with WFNA or IRFNA. TMEDA is employed in various industrial applications and is therefore readily available.

TMEDA melts at 214.5 K (−58.6 °C) and boils at 394.2 K (121 °C). These data from one source differ from the data from another source in Table 47. The heat of vaporization of TMEDA is  $\Delta_{\text{vap}}H^\circ = 42.2 \text{ kJ/mol} = 10.09 \text{ kcal/mol}$  at 298 K and 39.8 kJ/mol (9.51 kcal/mol) at 295–365 K.

TMEDA has been evaluated as a constituent in fuel mixtures with 2-*N,N*-dimethylaminoethylazide (DMAZ). Fuel mixtures of TMEDA with DMAZ, tris-(2-azidoethyl)amine (TAEA), or cyclic amine azides exhibit a synergistic effect when it comes to short ignition delays with IRFNA, shorter than those of any of the ingredients by themselves, an effect that was not predictable from review of each component's composition [236–238].

A wide range of aliphatic amines have been evaluated as hypergolic fuels for WFNA or RFNA, and the most promising of the 400 chemicals investigated were the low-molecular-weight ditertiary diamines [239, 240]. They possess wide liquid ranges (low freezing points, high boiling points), short ignition delays at temperatures as low as 219 K (−65 °F), low viscosities, good long-term storage stability, thermal stability at elevated temperatures ( $\geq 533 \text{ K} = \geq 500 \text{ °F}$ ), efficient combustion with RFNA, high density-specific impulse (Isp), ease of preparation, and low cost of raw materials. A group of diamines of the general structure

where  $n = 1$  through 4 plus tetramethylhexane-1,6-diamine was synthesized. It was found that in this series of diamines, the methylenediamine was unsatisfactory at room temperature and the hexane-1,6-diamine and 2-butyne-1,4-diamine were unsatisfactory at low temperatures. The diamines were found to be miscible with JP-4 in all proportions. The diamine with the most desirable properties similar to TMEDA and the runner-up was *N,N,N',N'*-tetramethylbutane-1,3-diamine,  $(\text{H}_3\text{C})_2\text{N}(\text{CH}_2)_4\text{N}(\text{CH}_3)_2$ ,  $\text{C}_8\text{H}_{20}\text{N}_2$ , TMBDA. Other diamines for which detailed physical properties were obtained were *N,N,N',N'*-tetramethylpropane-1,2-diamine, *N,N,N',N'*-tetramethylpropane-1,3-diamine, *N,N,N',N'*-tetramethylpropene-1,3-diamine, and *N,N,N',N'*-tetramethyl-1-butenediamine. Fourteen saturated ternary multiamines were synthesized and characterized, and three were tested in rocket engine firings: 1,2-bis(dimethylamino)ethane, 1,2-bis(dimethylamino)propane, and 1,3-bis(dimethyl-amino)propane.

Table 47: Physical properties of TMEDA and TMBDA in comparison to UDMH.

|                                        | TMEDA                   |                                                    | TMBDA                   |                                                     | UDMH                     |                          |

Data source: [240]

Table 47 gives the physical properties of TMEDA along with its  $C_4$  homologue TMBDA in comparison to the properties of UDMH. All of these are hypergolic fuels intended to be used with WFNA or RFNA.

The evaporation rates of TMEDA droplets suspended from a fiber in a temperature-controlled windowed oven were measured with and without addition of 10 or 20% of dissolved 1,2,4-triazole [241]. During heating, TMEDA started to evaporate at a temperature below its boiling point, and 1,2,4-triazole, a solid at room temperature, evaporated subsequently. Evaporation behaviors of TMEDA droplets with 10 and 20 mass-% of 1,2,4-triazole were studied at various temperatures. Bubbling and puffing were observed above 673 K (400 °C) in the case of the TMEDA containing 1,2,4-triazole. The rate of evaporation at the same temperature was substantially enhanced by increasing the concentration of 1,2,4-triazole.

### 12.1.1 Reactions of TMEDA

The mechanism of hypergolic ignition delays of TMEDA with WFNA or IRFNA has been studied [242, 243]. A three-stage hypergolic ignition process was revealed by both the temperature measurements in the drop tests and the pre-ignition products analysis in the confined interaction experiments. In the first stage, condensed-phase reactions take place between TMEDA and  $HNO_3$  upon their contact to form corresponding nitrate salts.

The dinitrate of  $N,N,N',N'$ -tetramethyl-1,2-diaminoethane was evaluated as a fuel for nitric acid-based monopropellants similar to CAVEA [244]. The melting point of the dinitrate salt is 493–494 K (220–221 °C).

Nitrate salts of TMEDA and TMBDA have been evaluated as fuels for nitric acid-based monopropellants.  $N,N,N',N'$ -tetramethylpropane-1,3-diamine dinitrate melted at 431 K = 158 °C = 317 °F, and  $N,N,N',N'$ -tetramethylbutane-1,3-diamine dinitrate melted at 389 K = 116 °C = 240 °F. Both salts are soluble in WFNA.

### 12.1.2 Safety Properties of TMEDA

The toxicity of TMEDA is substantially less than that of MMH. TMEDA was tested for potential mutagenicity in comparison to DMAZ. TMEDA was found not to be mutagenic in any of the bacterial strains tested (*Salmonella* TA98, TA100, TA1535, and TA1537 and *Escherichia coli* WP2uvrA), with or without metabolic activation [245]. TMEDA produced a positive response in structural chromosomal aberrations in Chinese hamster ovary (CHO) cells, with or without metabolic activation, but only at the highest concentration, 5 mg/mL. DMAZ and TMEDA, when tested *in vivo* in the CD-1 mouse at doses up to 500 and 250 mg/kg, respectively, did not induce micronuclei in bone marrow erythrocytes. DMAZ and TMEDA were negative for induction of chromosomal aberrations in CHO cells *in vitro* and in the *in vivo* mouse micronucleus assay.

## 12.2 Triethylenediamine

Triethylenediamine, CAS RN [280-57-9], is a tertiary heterocyclic amine in which all three bonds between two nitrogen atoms are linked by ethylene bridges:

It really belongs in the chapter on heterocyclic amines instead of here among the open-chain linear amines. This is a nearly spherical molecule, and its symmetry also has an effect on its physical properties (it has a very narrow liquid range and sublimates like camphor). The correct nomenclature for this molecule is 1,4-diazabicyclo[2.2.2]octane. It is also known under the trade name DABCO. Triethylenediamine forms colorless, hygroscopic crystals that melt at 431 K (158 °C) and boil (sublime) at 447 K (174 °C). It is soluble in water and alcohols. DABCO is used as a catalyst in the curing and foaming of polyurethane polymers. Triethylenediamine forms mononitrate and dinitrate salts as well as monoperchlorate and diperchlorate salts.

Fast thermolysis/FTIR spectroscopy of triethylenediammonium(2+) dinitrate  $[\text{HN}(\text{CH}_2\text{CH}_2)_3\text{NH}](\text{NO}_3)_2$  (DABCOD) and a new oxonium nitrate  $(\text{H}_3\text{O}^+\text{NO}_3^-)$  double salt of DABCOD were used to study reaction pathways during thermal decomposition of alkylammonium nitrates [162]. DABCOD produced no  $\text{HNO}_3$  vapor, but instead gave  $\text{CH}_2\text{O}$ , *N,N'*-dinitrosopiperazine and small fragments. These patterns are entirely consistent with the behavior observed for primary, secondary, and tertiary ammonium mononitrate salts in previous work. The presence of nitrosamines strongly increases the health hazard of the materials upon uncontrolled heating. No nitramines were detected as thermolysis products. Thermolysis of the oxonium nitrate double salts liberated  $\text{HNO}_3$  and  $\text{H}_2\text{O}$  at a relatively low temperature (333 K = 60 °C). Above this temperature, the thermolysis proceeded in the same way as that of pure DABCOD.

Triethylenediammonium(2+) diperchlorate can be prepared by slowly neutralizing a solution of triethylenediamine in water with 40%  $\text{HClO}_4$  [246]. Pyrolysis of triethylenediammonium diperchlorate can lead to *N*-methyl-*N'*-ethylpiperazine and *N,N'*-diethylpiperazine as decomposition products.

Triethylenediammonium(2+) diperchlorate forms double salts with two moles of ammonium perchlorate, which can be prepared by a facile one-pot reaction of AP,  $\text{HClO}_4$ , and triethylenediamine and have perovskite crystal structure [247]. The crys-

tals were characterized by XRD, FT-IR, and TG-DSC. The ternary salt had a more stable thermal decomposition temperature (658 K = 385 °C) than AP.

## 13 C<sub>26</sub> Non-Cyclic Multifunctional Amines

### 13.1 Tris(2-aminoethyl)amine

Tris(2-aminoethyl)amine, also known as 1,2-ethanediamine, *N,N*-bis(2-aminoethyl)-; *N1,N1*-bis(2-aminoethyl)-1,2-ethanediamine, TRIS, C<sub>6</sub>H<sub>18</sub>N<sub>4</sub>, N(CH<sub>2</sub>CH<sub>2</sub>NH<sub>2</sub>)<sub>3</sub>, CAS RN [4097-89-6] was used as the nitrate salt in some NASA-sponsored HAN-based monopropellant studies (*Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-Based Monopropellants”). Other applications for tris(2-aminoethyl)amine are as a chelator and water conditioning agent. It can be neutralized with three equivalents of nitric acid to yield tris(2-aminoethyl)ammonium trinitrate, [(N<sup>+</sup>H<sub>3</sub>CH<sub>2</sub>CH<sub>2</sub>)<sub>3</sub>N][NO<sub>3</sub><sup>-</sup>]<sub>3</sub>, C<sub>6</sub>H<sub>21</sub>N<sub>5</sub>O<sub>9</sub>, TRIN, TRN, TRN3, which has been tested as a substitute for triethanolammonium nitrate (TEAN) in liquid gun and rocket propellants. It is assumed that the three external amino groups in beta position from the central nitrogen atom would be protonated first. Theoretically it should be possible to form a tetranitrate in which the central nitrogen atom also becomes protonated, but it is not known whether this compound exists. Physical properties of tris(2-aminoethyl)amine are listed in Table 48.

**Table 48:** Physical properties of tris(2-aminoethyl)amine.

| Property                            | SI units                                | Other units                             |
|-------------------------------------|-----------------------------------------|-----------------------------------------|
| Molecular mass                      | 146.23 g/mol                            | 6.838 mol/kg                            |
| Density (predicted)                 | 1.002 ± 0.06 g/cm <sup>3</sup> at 293 K | 1.002 ± 0.06 g/cm <sup>3</sup> at 20 °C |
| p <i>K</i> <sub>a</sub> (predicted) | 10.00 ± 0.10 at 298 K                   | 10.00 ± 0.10 at 25 °C                   |
| Boiling point                       | 369–372 K                               | 96–99 °C                                |

### 13.2 Thermal Stability of TRN3

In DSC, TRN3 showed two weak endotherms at 372 and 435 K (99 and 162 °C) and decomposed immediately after melting at 575 K (302 °C). The exotherm peaked at 587 K (314 °C).

## 14 C<sub>7</sub> Multifunctional Amines

A tertiary amine fuel, *N,N,N',N'*-tetramethyl-1,2-diaminopropane (boiling point 411 to 412 K = 138 to 139 °C,  $n_D 1.4230$ ,  $\rho = 0.7900 \text{ g/cm}^3$ ) was proposed as rocket fuel [248].

The nitrate of this amine was evaluated as a fuel for nitric acid-based monopropellants (similar to CAVEA) [244]. The melting point of the dinitrate salt is 450–452 K (177–179 °C). The dinitrates of this amine and other tetramethyl C<sub>2</sub> through C<sub>8</sub> linear diamines were patented as solid propellant ingredients [249].

## 15 C<sub>8</sub> Multifunctional Amines

A theoretical rocket performance table published by Rocketdyne in the 1960s, which for many years has decorated the author's office wall, included performance data for a less frequently used amine, *N,N,N',N'*-tetramethyl-1,3-diaminobutane:

It appears to have been simply a theoretical exercise because otherwise there are no publications about this fuel. The dinitrates of this amine and other tetramethyl C<sub>2</sub> through C<sub>8</sub> linear diamines were patented as solid propellant ingredients [249, 250].

## 16 C<sub>10</sub> Multifunctional Amines

The dinitrate of *N,N,N',N'*-tetraethyl-1,2-diaminoethane was evaluated as a fuel for nitric acid-based monopropellants [244]. The melting point of the dinitrate salt is 415–416 K (142–143 °C). The same patent contains melting points of a dozen other tertiary multifunctional amine nitrates.

## 17 Other Tertiary Amines

The nitrate salts of various tertiary amines can be prepared from the corresponding chlorides by adding stoichiometric amounts of WFNA and driving off the HCl as an aqueous azeotrope until the reacting mixture is chloride-free, followed by pouring the mixture into an excess of acetone, and then filtering and drying the precipitate [251]. The nitrate salts thus prepared can be mixed with kerosene, more nitric acid, and an emulsifier to make a propellant mixture suitable for use in ramjets. The melting points of some of the tertiary alkylammonium nitrates are summarized in Table 49.

**Table 49:** Melting points of tertiary alkylammonium nitrates.

| Amine converted to nitrate salt                            | Mols of<br>HNO <sub>3</sub> | Mols of<br>amine | Yield<br>% | Melting point   |                 |
|------------------------------------------------------------|-----------------------------|------------------|------------|-----------------|-----------------|
|                                                            |                             |                  |            | K               | °C              |
| <i>N,N,N',N'</i> -tetramethylethane-1,2-diamine            | 0.608                       | 0.275            | 96.3       | 493–494         | 220–221         |

Data source: [251]

## 18 Unsaturated Aliphatic Amines

### 18.1 Unsaturated Alkenyl Aliphatic Amines

Allyl amine and diallyl amine,  $\text{H}_2\text{C}=\text{CH}-\text{CH}_2\text{NH}_2$  and  $(\text{H}_2\text{C}=\text{CH}-\text{CH}_2)_2\text{NH}$ , have been proposed as hypergolic rocket fuels, but they are not readily available. Ignition delays of these fuels, alone and in mixtures with triethylamine, with RFNA as the oxidizer were measured at NASA using a modified open-cup ignition test method [252].

### 18.2 Unsaturated Alkynyl Aliphatic Amines

MAF-2 was a rarely used hypergolic fuel mixture consisting of 42.6% propargyldiglycidylamine,  $\text{HC}\equiv\text{CCH}_2\text{N}(\text{CH}_2\text{OCHCH}_2)_2$ , 48.3% dipropargylglycidylamine,  $(\text{HC}\equiv\text{C}-\text{CH}_2)_2\text{N}(\text{CH}_2\text{OCHCH}_2)$ , and 9.1% tripropargylamine  $(\text{HC}\equiv\text{CCH}_2)_3\text{N}$ . The properties of MAF-2 and its constituents are listed in Table 50. The acetylenic triple bond and the oxiridine ring tension added energy to those fuels. The disadvantages of MAF-2 were high viscosity and poor ignition with RFNA.

The *USAF Propellant Handbook, Hydrazine Fuels, Volume 1* contains a unit with physical properties of MAF-2 from which the following properties were copied [184]. It also has two graphs showing the density and absolute viscosity of MAF-2 as a function of temperature. The density of MAF-2 as a function of temperature for the range 323 to

**Table 50:** Properties of alkynylamines and MAF-2 fuel mixture.

Data source: [184]

344 K (−50 to +71 °C) can be calculated using the equation

$$\rho = 1.2804 - 8.590 \times 10^{-4} T$$

where  $\rho$  is the density in g/cm<sup>3</sup> and  $T$  is the temperature in kelvin. The absolute viscosity of MAF-2 can be calculated from the equation

$$\log \mu = 8.6632 - 6714.4/T = 1.3537 \times \frac{10^6}{T^2}$$

where  $\mu$  is the viscosity in cPs and  $T$  is the temperature in kelvin.

Propargylamine can be prepared by reacting propargylphthalimide with a primary mono- or polyamine [253]. Propargylamine has a boiling point of 354–356 K (81–83 °C). Dipropargylamine has a boiling point of 326–329 K at 1.73–2.0 kPa (53–56 °C at 13–15 mm Hg). The density of dipropargylamine is 0.901 g/cm<sup>3</sup> at 293 K. Dipropargylamine can be prepared by reaction of propargylamine with propargylbromide while protecting one of the hydrogens with ethyl trifluoroacetate to prevent alkylation to the tertiary amine.

Dipropargylamine has a calculated heat of formation of 464 kJ/mol (111 kcal/mol). Tripropargylamine was prepared by addition of 2 mol propargyl bromide to propargylamine [254]. Tripropargylamine has a boiling point of 353–356 K at 1.73–2.0 kPa (80–83 °C at 13–15 mm Hg).

## 19 Azido-Substituted Amines

In many cases, hydrogen in alkyl groups of aliphatic amines has been replaced by explosophoric groups in order to improve one or several properties of the parent amine for rocket applications. The substitution is usually done with the intent to shorten ignition delays in hypergolic reactions and/or to improve specific impulse. Substituent groups that bring about the desired improvements are azido, nitro, cyano, and dinitramido groups.

Introduction of the azido group  $-N_3$  into aliphatic amines results in fuels with increased heat of combustion and improved rocket performance as fuels in bipropellant rockets. Several azido-substituted amines have been developed and tested as rocket fuels. Some of these azido molecules are so energetic that they can even decompose exothermally and can be used as monopropellants. Azidoalkanols are discussed in the chapter “Azido Compounds,” instead of in the chapter on alcohols and substituted alcohols because the properties of azidoalkanols are dominated by the azido group and not by the hydroxyl group.

In all the relatively stable azidoalkylamines, the azido group is linked to a central nitrogen atom by way of in-between carbon linkages. The most unusual azidoamines would be those in which the azido group is connected directly to an amino or amido nitrogen without intermediary carbon linkages, for instance azidoamine  $N_3NH_2$ , diazidoamine  $(N_3)_2NH$  and its anion  $(N_3)_2N^-$  (an analog to dinitramide), and eventually triazidoamine  $(N_3)_3N$ , an all-nitrogen compound. None of these azidoamines has been synthesized yet, but their molecular structures and energy levels have been calculated by computational chemistry methods [255].

### 19.1 2-Azidoethylamine

Azidoaminoethane, also known as  $\beta$ -azidoethylamine, 2-azidoethylamine, 2-azido-*N,N*-dimethylethanamine,  $N_3-CH_2-CH_2-NH_2$ ,  $C_2H_6N_4$ , is a clear liquid that boils at 320 K (47 °C) at 2.2 kPa (16.5 mm Hg) vacuum. It has a density of 1.0429 g/cm<sup>3</sup> at 298 K (25 °C) and a refractive index  $n_D^{25}$  of 1.4635. It ignites on contact with WFNA or RFNA.

### 19.2 *N,N*-Dimethyl-2-azidoethylamine (DMAZ)

2-Azido-*N,N*-dimethylethylamine, also known as dimethylaminoethyl azide, *N,N*-dimethyl-2-azidoethylamine, 2-azidoethyl-*N,N*-dimethylamine, 2-azido-*N,N*-dimethylethanamine, dimethylamine-2-ethylazide,  $(CH_3)_2NCH_2CH_2N_3$ ,  $C_4H_{10}N_4$ , DMAZ, CAS RN [86147-04-8] is a candidate to replace hydrazine fuels, especially MMH, in certain hypergolic fuel applications [256]. It can also decompose by itself in a monopropellant fashion and has been considered as a replacement for

hydrazine as a monopropellant (*Encyclopedia of Monopropellants*, chapter “Organic Monopropellants”). DMAZ has been tested with RFNA in bipropellant rocket engines.

When a fuel has a tertiary amine functionality and an azide functionality in the same molecular structure, it may have an ignition delay with WFNA or RFNA competitive with hydrazine fuels, and it has a superior density-specific impulse while probably being less toxic. The azide functionality can decompose exothermically with enough energy to sustain its decomposition in a monopropellant mode when heated. Several tertiary amine azido compounds have been synthesized, and their physical and ballistic properties were evaluated to determine their acceptability as hypergolic bipropellant fuels and liquid monopropellant gas generants. Although no hypergolic rocket engine testing was conducted, several small-scale liquid gas generator tests were performed. See also [257].

### 19.2.1 Preparation of N,N-Dimethyl-2-azidoethylamine

DMAZ can be prepared by azidation of 2-chloro-*N,N*-dimethylaminoethyl hydrochloride and neutralization of the intermediate, which is a two-step synthesis of the fuel. A kinetic study on the production reaction of DMAZ was done to optimize the yield of the process [258]. The methods of excess and equimolar concentrations were used for the measuring dependency of the reaction rate on reactants and temperature. The results showed that the reaction was first order with respect to reactants, and an integral method confirmed the reaction rate equation. The rate-determining step was extremely endothermic, with an activation energy of 90 kJ/mol. The raw product can be purified by vacuum distillation [259].

Two different synthesis routes for 2-azido-*N,N*-dimethylethanamine (DMAZ) were compared, and the product was obtained via one of the methods with a purity of better than 99% [260]. The structure and purity were confirmed by FTIR, GC-MS, and  $^1\text{H-NMR}$ .

There are at least six synthesis methods for making DMAZ [261–263].

To improve the yield of DMAZ synthesis, the kinetics of the reaction of 2-chloro-*N,N*-dimethylethylamine hydrochloride with sodium azide in aqueous solution were studied using UV absorption spectrometry [264]. The results showed that the reaction can be considered a second-order reaction. The reaction rate constants were  $1.337 \times 10^{-3}$ ,  $3.403 \times 10^{-3}$ , and  $7.082 \times 10^{-3} \text{ L} \cdot \text{mol}^{-1} \cdot \text{min}^{-1}$ , respectively, at 337, 347, and 357 K. The apparent activation energy ( $E_a$ ) was 83.5 kJ/mol, and the pre-exponential factor was  $1.19 \times 10^{10} \text{ L} \cdot \text{mol}^{-1} \cdot \text{min}^{-1}$ .

For most applications, DMAZ must be water-free. Water can be removed by adsorption on zeolites, calcium chloride, or nano-particles [265]. The best water adsorption from DMAZ was obtained by  $\text{CaCl}_2$  adsorbent within 10 min.

DMAZ that would otherwise be lost with wastewater dumped overboard can be recovered by adsorption on zeolites or activated carbon [266].

DMAZ can be dehydrated by water adsorption on 3A molecular sieves [267]. Experiments showed that the optimum adsorption capacity (191.3 mg/g) was obtained

with contact time = 150 min, liquid/solid ratio = 10 : 1, initial concentration of water = 3 mass-%, and agitating rate = 150 rpm. Thermal stability and regeneration behavior of the zeolite adsorbent were investigated using XRD and TGA/DSC. It was found that the best regeneration occurred in the range of 523–573 K (250–300 °C), and the zeolite structure was stable up to 673 K (400 °C). Thermal analysis verified that DMAZ molecules cannot diffuse into 3A zeolite pores.

A cobalt-doped silica (Co-SiO<sub>2</sub>) layer was synthesized in a sol-gel process as the mesoporous layer overlaid in three-step, six-step, and ten-step coating on a mullite support membrane [268]. The membranes were used in pervaporation experiments to dehydrate DMAZ containing 5 mass-% water. In dehydration tests, the membrane permeate flux decreased and its separation factor increased. During the first initial hours, it reached a steady state and subsequently remained constant.

### 19.2.2 Physical Properties of N,N-Dimethyl-2-azidoethylamine

The physical properties of DMAZ have been compared to the physical properties of MMH, which it was intended to replace in hypergolic bipropellant combinations [269] (Table 51).

A comparison shows that in all of the crucial parameters, DMAZ is generally similar to MMH. The enthalpy of formation of DMAZ is considerably higher than that of MMH and would suggest good performance as a rocket propellant.

A technique for computationally determining the thermophysical properties of high-energy-density propellants that combines quantum mechanical and molecular dynamic calculations and group additivity methods was used to determine thermophysical properties for quadricyclane and DMAZ [270, 271]. The modified force-field approach provided results that more accurately matched experimental data than the unmodified approach. In both cases, the use of high-energy-density fuels in bipropel-

**Table 51:** Comparison of physical properties of DMAZ and MMH.

| Property                                | DMAZ   | MMH    |
|-----------------------------------------|--------|--------|
| Molecular mass, g/mol                   | 114.15 | 46.07  |
| Enthalpy of formation, liquid, cal/g    | +586   | +284   |
| Enthalpy of formation, liquid, kcal/mol | +66.89 | +13.08 |
| Enthalpy of formation, liquid, kJ/mol   | +279.9 | +54.74 |
| Boiling point, °C                       | 135    | 87.65  |
| Freezing point, °C                      | −68.9  | −52.37 |
| Density, g/cm <sup>3</sup>              | 0.993  | 0.87   |
| Viscosity, centipoise                   | 2      | 0.775  |
| Surface tension, dyn/cm                 | 25     | 33.83  |
| Flash point, Tag, °C                    | 29.4   | 17     |

Note: All values measured at 298 K = 25 °C unless otherwise stated

Data source: [269]

lant combinations provides reductions in vehicle mass compared to industry-standard propellants.

Summaries of the physical and chemical properties of DMAZ are in [272–275].

### 19.2.2.1 Density of DMAZ

The density quoted by other sources ( $0.993 \text{ g/cm}^3$  at  $298 \text{ K} = 25^\circ\text{C}$ ) does not match that found from the curve fit ( $\rho(\text{g/cm}^3) = 0.9517 - 0.0010T$ ), which gives  $0.9267 \text{ g/cm}^3$  at  $298 \text{ K} = 25^\circ\text{C}$  [269]. Using other density/temperature data gives a density of  $0.9257 \text{ g/cm}^3$  at  $298 \text{ K} = 25^\circ\text{C}$ . The quoted curve fit

$$\rho = 0.9517 - 0.0010T$$

suffers from truncation errors in the formula, resulting in errors increasing with temperature (nearly 0.4% at  $0^\circ\text{C}$ ). The fit

$$\rho = 0.9517 - 0.00104T$$

would be better. The density predicted by molecular orbital calculations is higher than the actual measured density (Figure 6).

**Figure 6:** DMAZ experimental and predicted density vs. temperature. (Reproduced and modified from [276] with permission from Dr. Timothy Kokan on 3 July 2020.)

### 19.2.2.2 Vapor Pressure of DMAZ

The vapor pressure of DMAZ can be expressed by the equation

$$\log p_{10} = 0.4756 + 0.02434T - 0.0000629T^2 + 0.000000116T^3$$

where  $p$  is the pressure in mm Hg and  $T$  is the temperature in kelvin.

19.2.2.3 Kinematic Viscosity of DMAZ

The viscosity of DMAZ can be expressed by the equation

$$\eta = 0.998 - 0.0108T + 0.00005T^2$$

where  $\eta$  is the viscosity in cSt and  $T$  is the temperature in kelvin.

The dynamic viscosity shown in Table 2 from Reference [273] (2 cPs at 298 K = 25 °C) does not match the data in Table 4 of the same report (interpolation would give 0.7034 cPs at 298 K = 25 °C) [269].

Table 52: Measured shear viscosity of DMAZ

| Pressure<br>atm | Temperature<br>K | Viscosity $\mu$<br>cPs |
|-----------------|------------------|------------------------|
| 1.0             | 293.25           | 0.721                  |
| 1.0             | 313.00           | 0.564                  |
| 1.0             | 333.10           | 0.456                  |
| 1.0             | 353.05           | 0.379                  |
| 1.0             | 368.05           | 0.335                  |
| 1.0             | 387.35           | 0.284                  |
| 1.0             | 406.05           | 0.255                  |
| 8.0             | 406.35           | 0.249                  |
| 15.0            | 421.55           | 0.235                  |
| 19.0            | 438.95           | 0.209                  |

Data source: [276]

Figure 7: DMAZ kinematic viscosity vs. temperature. (Reproduced and modified from [276] with permission from Dr. Timothy Kokan on 3 July 2020.)

The shear viscosity of DMAZ was measured using a high-pressure Cannon-Fenske viscometer (Table 52) (Figure 7). The ASTM standards D445-04 and D446-04 were followed to obtain viscosity measurements.

#### 19.2.2.4 Thermal Conductivity of DMAZ

The thermal conductivity was measured using a relative transient hot-wire method with a Pyrex capillary filled with mercury. Thermal conductivity predicted by an additivity method was higher than actual measured thermal conductivity (Table 53) (Figure 8).

**Table 53:** Measured thermal conductivity of DMAZ.

| Pressure<br>atm | Temperature<br>K | Thermal conductivity $\lambda$<br>$\text{W m}^{-1} \text{K}^{-1}$ |
|-----------------|------------------|-------------------------------------------------------------------|
| 1.0             | 297.40           | 0.133                                                             |
| 1.0             | 324.90           | 0.125                                                             |
| 1.0             | 349.30           | 0.118                                                             |
| 8.0             | 374.30           | 0.112                                                             |
| 11.0            | 398.50           | 0.107                                                             |
| 19.0            | 425.30           | 0.101                                                             |

### 19.2.2.5 Solubility and Volatility of DMAZ

Henry's law constants at 298 K for four 2-azidoethanamine hypergols and three aliphatic amines were estimated via a density functional theory/polarizable continuum model (DFT/PCM) method as input for modeling their transport through the environment in case of accidental spills [277]. The four azidoethanamines were 2-azido-*N,N*-dimethylethanamine (DMAZ), 2-azido-*N*-methylethanamine, 1-(2-azidoethyl)pyrrolidine, and 4-(2-azidoethyl)morpholine, and the three aliphatic amines were dimethylamine, trimethylamine, and 1-methylpyrrolidine. The estimates for the three aliphatic amines were all within a factor of 5 of measured values that had been reported for them, but all were somewhat low. The estimates from both methods suggest that the volatilization of these compounds from water will be negligible.

### 19.2.2.6 Thermodynamic Properties of DMAZ

#### Specific Heat of DMAZ

The heat capacity of DMAZ as a function of temperature was measured using a DSC method (Table 54).

**Table 54:** Heat capacity of DMAZ

| Temperature |             | Heat capacity                     |                                      |
|-------------|-------------|-----------------------------------|--------------------------------------|
| K           | °C          | J g <sup>-1</sup> K <sup>-1</sup> | cal g <sup>-1</sup> °C <sup>-1</sup> |
| 223 to 273  | -50 to 0 °C | 1.22                              | 0.29                                 |
| 293         | 20          | 1.4                               | 0.33                                 |
| 303         | 30          | 1.6                               | 0.38                                 |
| 313         | 40          | 1.8                               | 0.43                                 |
| 323         | 50          | 2.2                               | 0.53                                 |
| 333         | 60          | 2.8                               | 0.67                                 |
| 343         | 70          | 3.8                               | 0.91                                 |
| 353         | 80          | 4.7                               | 1.12                                 |
| 363         | 90          | 5.6                               | 1.34                                 |

Data source: [272]

In a different set of experiments, the specific heat of DMAZ was also measured using a differential scanning calorimeter, but the data in these two tables are quite different (Table 55). It is not known which set of data is more accurate. The samples were weighed using a thermogravimetric analyzer. The ASTM standard E1269-04 was followed to obtain specific heat measurements.

**Table 55:** Measured specific heat of DMAZ.

| Pressure<br>atm | Temperature<br>K | Heat capacity $c_p$<br>$\text{J g}^{-1} \text{K}^{-1}$ |
|-----------------|------------------|--------------------------------------------------------|
| 1.0             | 320              | 1.782                                                  |
| 1.0             | 325              | 1.812                                                  |
| 1.0             | 330              | 1.817                                                  |
| 1.0             | 335              | 1.819                                                  |
| 1.0             | 340              | 1.820                                                  |
| 1.0             | 345              | 1.823                                                  |
| 1.0             | 350              | 1.823                                                  |
| 1.0             | 355              | 1.825                                                  |
| 1.0             | 360              | 1.825                                                  |
| 1.0             | 365              | 1.825                                                  |
| 1.0             | 370              | 1.830                                                  |

### Enthalpy of Formation of DMAZ

A new technique for determining thermophysical properties of potential new rocket engine propellants used a combination of three different computational methods to predict these properties [271, 276, 278, 279]. Quantum mechanics and molecular dynamics were used to model new propellants at a molecular level in order to calculate density, enthalpy, and entropy. Additivity methods were used to calculate the kinematic viscosity and thermal conductivity of new propellants. This new technique was validated by comparing results for two fuels: quadricyclane and 2-azido-*N,N*-dimethylethanamine (DMAZ). In each case, the new technique was better than the best current computational methods at accurately matching the experimental data of the two propellants.

The enthalpy and entropy of formation of two high-energy-density matter (HEDM) fuel compounds, DMAZ and quadricyclane, are provided in Table 56.

**Table 56:** Thermodynamic properties of liquid DMAZ and liquid quadricyclane.

| Compound      | Enthalpy of formation $\Delta H_f$ |          | $\Delta S_f$ at 101 kPa           | $\Delta S_f$ at 1 atm                |
|---------------|------------------------------------|----------|-----------------------------------|--------------------------------------|
|               | kJ/mol                             | kcal/mol | $\text{J mol}^{-1} \text{K}^{-1}$ | $\text{cal mol}^{-1} \text{°C}^{-1}$ |
| Quadricyclane | +302                               | +72.2    | 167                               | 39.9                                 |
| DMAZ          | +280                               | +66.9    | 154                               | 36.8                                 |

Data source: [276]

### 19.2.2.7 Molecular Structure of DMAZ

The molecular structure of DMAZ is shown in Figure 9.

**Figure 9:** Molecular structure of DMAZ.

### 19.2.2.8 Computational Chemistry Studies of N,N-Dimethyl-2-azidoethylamine Molecule

Non-local density functional theory utilizing exchange-correlation functionals was used to characterize the geometric parameters and normal modes of 12 equilibrium conformations of DMAZ [280]. An experimentally acquired, mid-IR absorption spectrum of DMAZ vapor was analyzed and compared to computational results. The analysis indicated that the relative populations of DMAZ conformers in a room-temperature sample do not deviate significantly from expectations based on a Boltzmann distribution calculated from their theoretically determined zero-point corrected energies. The most abundant conformer most likely has the central nitrogen atom of the azido group aligned over the amine lone-pair electrons, a configuration likely to inhibit proton transfer to the amine site.

DMAZ had shown some promise as a less toxic replacement for MMH in hypergolic combinations, but the ignition delays observed for IRFNA/DMAZ were much longer (i.e., more hazardous) than those for IRFNA/MMH. For comparison, 2-azidocyclopropaneamine has two stereochemically distinct isomers, one of which prevents the azide group from “shielding” the amine lone-pair electrons from proton attack. The other promotes such shielding. Since shielding likely influences the manner in which nitric acid reacts with amine–azide fuels, the ignition delays for the isomers may be different, and it is possible that one of the isomers will yield shorter ignition delays than DMAZ [281, 282].

Molecular dynamics simulations to estimate the densities and heats of vaporization of aliphatic compounds with both azido and amino functional groups led to theoretical densities of these liquids that tend to be slightly overpredicted. Previously obtained DFT calculations suggested that this overprediction may be due to the attractive interaction between the amine nitrogen and the middle nitrogen of the azide group being smaller than modeled by the force field. The temperature dependence of

the density of DMAZ was well predicted, but melting point and boiling point estimates were far off the reality [283].

In an attempt to find structural features of 2-azidoethanamines that correlate with their hypergolic ignition delays, DFT-based quantum mechanics calculations were performed to characterize equilibrium configurations of two secondary 2-azidoethanamines: 2-azido-*N*-cyclopropylethanamine (CPAZ) and 2-azido-*N*-methylethanamine (MMAZ) [284]. The former is hypergolic with IRFNA, whereas the latter is not. Geometries and normal modes for MMAZ conformers and CPAZ conformers were compared to geometries and normal modes obtained previously for the hypergolic, tertiary 2-azido-*N,N*-dimethylethanamine (DMAZ).

The applicability of semi-empirical models for estimating the gas-phase enthalpies of formation, enthalpies of vaporization, and enthalpies of sublimation of azide-functionalized aliphatic compounds was evaluated [285]. Enthalpies of vaporization estimates for azide-functionalized compounds were in reasonable agreement with values derived from experiments and from molecular dynamics simulations. Best estimates were obtained for a set of compounds with multiple azide groups that was synthesized by the U.S. Army Armament Research, Development and Engineering Center (ARDEC).

The proton affinity and base strength of beta-substituted ethanamines determine the stability of salts of these bases and degradation mechanisms of spilled propellants in the soil. Aqueous-phase dissociation constants ( $K_a$ ) for the conjugate acids of such beta-substituted ethanamine bases can be measured experimentally or predicted from computations. Aqueous-phase dissociation constants ( $K_a$ ) for the conjugate acids of a group of six 2-azidoethanamine bases ( $R_1N(R_2)CH_2CH_2N_3$  [1:  $R_1 = CH_3$ ,  $R_2 = H$ ; 2:  $R_1 = CH_3$ ,  $R_2 = CH_3$ ; 3:  $R_1 = CH_2CH_3$ ,  $R_2 = CH_2CH_3$ ; 4:  $R_1/R_2 = -CH_2-CH_2CH_2CH_2-$ ; 5:  $R_1/R_2 = -CH_2CH_2OCH_2CH_2-$ ; 6:  $R_1 = CH_2CH_3$ ,  $R_2 = CH_2CH_2N_3$ ]) were measured and were found to fall between those for analogous unfunctionalized and cyano-functionalized ethanamines [286]. The Gibbs free energies of aqueous-phase (equilibrium) conformers of the bases and their conjugate acids were determined via a DFT/PCM method. See also [287].

### 19.2.3 Chemical Properties of *N,N*-Dimethyl-2-azidoethylamine

#### 19.2.3.1 Thermal Stability of *N,N*-Dimethyl-2-azidoethylamine

A laboratory-scale flow reactor was used to subject small amounts (approximately 1 mL) of deoxygenated fuels, including DMAZ, to controlled conditions of temperature and residence-time-at-temperature at constant pressure (3.44 MPa = 34 atm) in the liquid or supercritical phase [288]. The reactor was made from CRES-316 HPLC tubing. The thermal stability of the fuels as well as the thermal fragmentation products of each fuel were measured using an in-line analytical system, as well as off-line GC analysis of products. Some of the candidate materials tested (DMAZ, quadricyclane, and bicyclopropylidene) showed only marginal thermal stability, with major decom-

position occurring below 673 K (400 °C) with only ~3 s residence time. Other candidate fuels (JP-10, RP-1, RG-1, RJ-6, and RJ-7) showed excellent thermal stability and little decomposition even at 873 K (600 °C). Results showed the pyrolytic stability of candidate materials relative to each other and provided insights into the mechanisms of thermal decomposition for specific fuel candidates.

Computational quantum mechanics was used to characterize species and transition states for anticipated H-atom abstraction and scission reactions involving DMAZ and/or 1,2-bis(dimethylamino)ethane (TMEDA) and their decomposition products [289]. Two reaction types were shown to be a reasonable basis for estimating the thermochemical properties of (equilibrium) reactants and products. Based on comparisons with results obtained from other calculations, the method appeared to underpredict the energies of transition states relative to reactant asymptotes.

As part of modeling of DMAZ decomposition (as well as the decomposition of other azide-functionalized energetic materials), postulated reaction paths were characterized via *ab initio* and DFT quantum chemical calculations [290, 291]. Four types of reactions were characterized: (1) simple scission of C—H, C—N, and C—C bonds, (2) N—N<sub>2</sub> bond fission via either concerted (synchronous) [DMAZ → singlet imine(R<sub>2</sub>C=NH) + N<sub>2</sub>] or stepwise (asynchronous) [DMAZ → nitrene intermediate R—N: + N<sub>2</sub>] steps, (3) HN<sub>3</sub> molecular elimination with the formation of dimethylaminoethylene, and (4) N<sub>2</sub> elimination with the formation of molecules with three-member or four-member heterocyclic rings. N—N<sub>2</sub> bond fission reactions were found to have the lowest energy barriers.

#### 19.2.3.2 Storability of N,N-Dimethyl-2-azidoethylamine

Elevated temperature *N,N*-dimethyl-2-azidoethylamine (DMAZ) storage tests under N<sub>2</sub> at a pressure of 3 bar and a moisture content of 0.05 mass-% H<sub>2</sub>O obtained a sigmoid-shaped decomposition curve and revealed that the decomposition reaction is auto-catalytic. Rate constants were measured for the first-order incipient reaction and the following auto-catalytic reaction. Modeling of the decomposition rate showed that the predicted shelf life of DMAZ was only 7.73 years at 298 K (25 °C) [292]. During the accelerated aging tests between 333 and 363 K (60 and 90 °C), the samples' color became gradually yellowish and ultimately black. Moisture contamination shortened the shelf life even further.

#### 19.2.3.3 Reactions of N,N-Dimethyl-2-azidoethylamine

*N,N*-Dimethyl-2-azidoethylamine ignites hypergolically with WFNA, RFNA, and high-test peroxide (HTP). Hypergolic ignition of DMAZ will be discussed in a future *Encyclopedia of Hypergolic Bipropellant Combinations*. The ignition of DMAZ with HTP can be improved by dissolving metal salts in the fuel [293]. As a base, DMAZ forms stable salts with many acids.

### 19.2.3.4 Salts Derived from *N,N*-Dimethyl-2-azidoethylamine

In the pursuit of higher heats of formations for low-volatility ionic liquids as replacements for MMH, energetic ionic liquids based on DMAZ as well as azide counter-anion-based ionic liquids were developed [294]. Energetic ionic liquids that contain the quaternary 2-azidoethyl-*N,N,N*-trimethylammonium cation coupled with nitrocyanamide, dicyanamide, dinitramide, or azide anions were synthesized in good yields by metathetical reactions. These ionic liquids exhibited desirable hypergolic activity with such oxidizers as 100% nitric acid and dinitrogen tetroxide.

These azide-based energetic ionic liquids were obtained either through metathetical reactions with silver azide (Reaction 1) or through direct neutralization with hydrazoic acid (Reactions 2 and 3). Of the 11 salts presented, all but one could be classified as ionic liquids with melting points below 373 K (100 °C), with several classifying as room-temperature energetic ionic liquids. Ignition-delay drop tests of several compounds with  $\text{N}_2\text{O}_4$  and WFNA exhibited hypergolicity. Among the room-temperature

energetic ionic liquids, products of Reaction 1c and Reaction 1a showed the shortest ignition-delay times for WFNA (8 and 16 ms, respectively). Despite not being room-temperature energetic ionic liquids, the products of Reaction 2 ( $T_m$  80 °C, impact sensitivity >40 J, WFNA hypergolic,  $N_2O_4$  explosion) and Reaction 3 ( $T_m$  75 °C, impact sensitivity >40 J, WFNA hypergolic) were reported as the first azide-based ionic liquids exhibiting hypergolicity. Both were hypergolic with  $N_2O_4$ , and triethylammonium azide was found to explode when exposed to WFNA. Both of these compounds are extremely hygroscopic.

Other azidoalkylamines can also be converted to energetic salts. Salts formed from 1,3-diazo-2-(azidomethyl)-2-propylammonium cations with nitroiminotetrazolate anions have been characterized by spectroscopy and single-crystal XRD [295]. The heats of formation and the detonation pressures and velocities were calculated. The silver salts were obtained by the metathesis of sodium dicyanamide and potassium dinitramide with silver nitrate in aqueous solution. Other salts based on the 1,3-diazo-2-(azidomethyl)-2-propylammonium cation and anions, such as nitrate, perchlorate, picrate, 3-nitro-5-oxo-1,2,4-triazolide, and 5-nitroiminotetrazolate, as well as dicyanamide and dinitramide, have been prepared and characterized.

Four ionic liquids were synthesized through a metathesis reaction of quaternized *N,N*-dimethyl-2-azidoethylamine with different alkyl chain lengths with silver dicyanamide [296]. The density, dynamic viscosity, and thermal properties of these ionic liquids were measured over a wide temperature range. When the effect of the alkyl chain length on the physicochemical properties was studied, it was found that density decreased while dynamic viscosity and molar heat capacity increased with increasing number of carbon atoms in the alkyl chain. The density showed a linear decrease with temperature, and the dynamic viscosity decreased with temperature. No melting points could be found for these four ionic liquids except for a glass transition temperature ( $T_g$ ). The  $T_g$  values were 184 to 171 K (−89 to −102 °C). The exothermic decomposition temperatures of these four ionic liquids ranged from 514 to 515 K (241 to 242 °C), independent of the alkyl chain length.

#### 19.2.4 Fuel Mixtures Containing *N,N*-Dimethyl-2-azidoethylamine

Various fuel mixtures of DMAZ with other amines provide short ignition delays and improve overall propellant properties. Such mixtures may contain *N,N,N',N'*-tetramethylethylenediamine (TMEDA) or tris(2-azidoethyl)amine [238, 297].

#### 19.2.5 Combustion and Flammability Properties of DMAZ

The lower flammable limit (LFL) of DMAZ has been determined to be 1.3 vol-% in air, and the upper flammable limit (UFL) is greater than 22.4 vol-% in air. Because DMAZ can decompose like a monopropellant, the UFL may even extend to 100% DMAZ vapor.

### 19.2.6 Materials Compatibility with DMAZ

DMAZ is compatible with most materials that are also compatible with organic amines, but it is more reactive with some materials.

### 19.2.7 Disposal of DMAZ

Surplus DMAZ that needs to be destroyed can be diluted with kerosene and burned in open pans.

An investigation of the chemical treatment of smaller quantities of DMAZ waste under laboratory conditions included reduction with tin (Sn) in hydrochloric acid (HCl), reduction with stannous chloride ( $\text{SnCl}_2$ ) in methanol, reduction with nickel–aluminum alloy (Raney nickel) in NaOH solution, and reduction with aluminum in NaOH solution.

Various reducing agents, Raney-nickel Al/Ni alloy in caustic 0.5-M NaOH, Al powder in 0.5-M NaOH, stannous chloride in methanol, and granular tin metal in concentrated hydrochloric acid were tested for the destruction of DMAZ and other hypergolic fuels [298]. DMAZ was reduced to *N,N*-dimethylethylenediamine in these tests.

DMAZ can be hydrolyzed in water in an autoclave at high temperatures and pressures [299, 300]. The hydrothermolysis of the water-soluble alkyl azide dimethyl-2-azidoethylamine was studied at 473–523 K (200–250 °C) and 275 bar in real time by flow-reactor FTIR spectroscopy. The kinetics of DMAZ decomposition by  $\text{N}_3^-$  formation represents only a minor reaction pathway (8% at 523 K = 250 °C). The main channel is loss of  $\text{N}_2$ , whose presence was determined by mass spectrometry. The Arrhenius parameters for decomposition by the two routes were  $E_a = 59 \text{ kJ/mol} = 14.1 \text{ kcal/mol}$  and  $\ln(A, \text{s}^{-1}) = 10.7$  for the  $\text{N}_2$  channel and  $E_a = 73 \text{ kJ/mol} = 17.4 \text{ kcal/mol}$  and  $\ln(A, \text{s}^{-1}) = 11.8$  for the  $\text{N}_3^-$  channel. Because of further reactions, the organic products could not be identified, but  $(\text{CH}_3)_3\text{N}$  appeared to be a major product. The  $\text{N}_3^-$  ion was found to be stable in water, at least to 613 K (340 °C).

DMAZ-contaminated wastewater that needs to be decontaminated before it can be released to surface waters can be purified by adsorption on zeolites or activated carbon [266]. The effects of various parameters, including the initial concentration of DMAZ, contact time, and adsorbent dosage on the DMAZ sorption efficiency, were examined, and the optimum experimental conditions were determined. DMAZ adsorption efficiencies of 60, 23, and 45% were obtained by ZSM-5, NaY zeolites, and activated carbon, respectively. It was observed that 15, 51, and 41 g of DMAZ could be removed by a unit mass of NaY zeolite, ZSM-5 zeolite, and activated carbon, respectively.

The photocatalytic activity of  $\text{TiO}_2$  deposited on expanded clay aggregate granules was determined for degradation of DMAZ in water, with mercury lamps as UV sources [301]. The results showed that the efficiency of photodegradation improved with increasing initial concentration of DMAZ and that the rate of DMAZ conversion increased with higher pH value and catalyst dosage. Under optimum conditions, a single-pass

degradation of 54.7% for DMAZ could be achieved. A first-order rate kinetic model presented good agreement with the experimental data.

### 19.2.8 Toxicity of DMAZ

It was difficult to prove that DMAZ was less toxic than MMH, which it was meant to replace.

The acute inhalation toxicity of DMAZ was determined in single-concentration studies using a minimum number of mice [274]. Initial 1-h exposures at levels of 2 mg/L (429 ppm), 9.2 mg/L (1973 ppm), and 20 mg/L (4289 ppm) showed that the low and mid-range levels could be tolerated for 1 h, but the high level was fatal in 40 min. A follow-up test was done with three exposed (1973 ppm for 1 h) and two control (unexposed) mice. The exposed mice showed signs of irritation around the eyes during exposure, but during the 14-d post-exposure observation period, the exposed mice gained weight similarly to the unexposed mice, and at necropsy no significant changes were noted by gross observations of the internal organs. It was concluded that the 1-h lethal concentration is greater than 1973 ppm but less than 4289 ppm, which rates this material as “toxic by inhalation” according to the guidelines of the U.S. Occupational Health and Safety Administration.

2-Dimethylaminoethyl azide (DMAZ, 99.3% pure) was tested for its potential to induce micronucleated polychromatic erythrocytes (MPCE) in the bone marrow cells of mice [302]. Male and female mice were dosed orally at 125, 250, and 500 mg DMAZ/kg body weight. Animals were euthanized approximately 24 or 48 h after dosing. The percentage of polychromatic erythrocytes (PCE) and the frequency of MPCE were determined at 24 and 48 h. There were no statistically significant increases in the number of MPCE in the treated groups when compared to the concurrent control group. These results indicated that DMAZ would not cause chromosome damage in the *in vivo* mouse micronucleus assay; therefore, it is not considered to be a clastogenic agent.

2-dimethylaminoethyl azide (DMAZ, 99.3% pure) was tested for mutagenic potential with *Salmonella typhimurium* strains TA 98, TA 100, TA 1535, and TA 1537 and *Escherichia coli* strain WP2uvrA by plate-incorporation method at doses up to 5000 micrograms/plate both in the presence and absence of S9 mix [303]. The results showed that DMAZ produced positive response in the TA 100 and TA 1537 strains, both with and without metabolic activation from S9 addition. No positive response was observed with any of the remaining tester strains with or without activation.

DMAZ was tested for potential mutagenicity in comparison to a tertiary amine, TMEDA. DMAZ did not produce any mutagenic effects at concentrations up to 5 mg/plate in the TA98 and TA1537 strains of *Salmonella typhimurium* or in an *E. coli* strain (WP2uvrA), with or without metabolic activation, but it did produce a positive response in the TA100 and TA1535 strains, both with and without metabolic activation [245]. DMAZ did not induce structural chromosomal aberrations at levels up to 5 mg/mL in Chinese hamster ovary (CHO) cells, with or without metabolic

activation. DMAZ, when tested *in vivo* in the CD-1 mouse at doses up to 500 and 250 mg/kg, respectively, did not induce micronuclei in bone marrow erythrocytes. These studies demonstrated that DMAZ is mutagenic in specific strains of *Salmonella*. However, it was negative for induction of chromosomal aberrations in CHO cells *in vitro* and in the *in vivo* mouse micronucleus assay.

### 19.2.9 Safety Properties of DMAZ

DMAZ has been subjected to the following safety tests [304]:

|                                |                                              |
|--------------------------------|----------------------------------------------|
| Card-gap test                  | Negative at zero cards                       |
| Drop-weight impact sensitivity | Negative at 165 kg-cm                        |
| Friction sensitivity           | Negative at 3.44 MN/m <sup>2</sup> (500 psi) |

The azido group in DMAZ may cause this compound to be sensitive to some external stimuli. Various conventional tests as well as computer codes were used to investigate the sensitivity of DMAZ to external stimuli such as impact, shock wave, Koenen test, burning, and electrostatic discharge sensitivity [305]. The results showed that DMAZ is not sensitive to impact, direct flame, or shock-wave initiation, but it has moderate and high sensitivity to heat in confined volume and electrostatic discharge, respectively.

### 19.2.10 Environmental Fate and Transport of DMAZ

Quantitative structure–property relationships (QSPRs) commonly employed as input for fate, transport, and effect modeling of hazardous materials in the environment can be predicted by computational methods. The reliability of QSPR estimates was examined for two classes of compounds considered as MMH replacements: (1) saturated tertiary multiamines and (2) ethanamine azides [306]. QSPRs contained in a program provided by the U.S. Environmental Protection Agency yielded reasonable estimates for amine normal boiling points, (ambient) vapor pressures, octanol–water partition coefficients, water solubilities, and air–water partition coefficients, but the estimates for azides were poor, or there were insufficient data with which to validate them. Alternative methods for estimating azide normal boiling points and vapor pressures were sought. Similar methods were used for predicting aquatic toxicity of these compounds to fish (LC50, 96 h), *Daphnia* (LC50, 48 h), and algae (EC50, 96 h).

### 19.2.11 Applications of DMAZ

It appears that DMAZ as a hypergolic rocket propellant fuel has been evaluated in many countries, including China [307].

### 19.2.11.1 Gelled DMAZ

Much work has been done on gelled MMH, and similar work was done on MMH replacements. In 2007, the U.S. Army awarded a Small Business Innovation Research contract to develop gelled azide amine fuels that would be less prone to leakage if the fuel tank were punctured by shrapnel [308].

Fumed silica as a gelling agent is not readily wetted by DMAZ, and conventional kitchen-type rotary mixers do not give uniform gels. Improved dispersion of gellant and added metal powder were achieved with resonant acoustic mixing [309]. The rheology and high-gravity centrifuge stability of DMAZ gelled with EH-5 fumed silica and metallized with nano-aluminum L-Alex powder were measured with different gelling agent loadings, but with mostly the same metal loading of ~30%. A surfactant was used to help wet the nanoparticles to aid in uniform dispersion in the gelled propellant.

### 19.2.11.2 DMAZ as a Monopropellant

Many azido-substituted alkylamines have been developed and tested as rocket fuels. Some of these azido molecules are so energetic that they can even decompose exothermally and can be used as monopropellants. DMAZ can also decompose by itself in a monopropellant fashion and has been considered as a replacement for hydrazine as a monopropellant. Catalysts have been sought (without success) that might initiate the decomposition of DMAZ as a monopropellant at room temperature, not requiring any pre-heating to initiate the decomposition reaction.

## 19.3 Other Azidoalkylamines

Pyrrolidinylethylazide, 2-azidoethylpyrrolidine,  $C_6H_{12}N_4$ , PYAZ,  $M = 140.19$  g/mol, has been proposed as an MMH replacement and is also mentioned in several patents [236, 310, 311].

It has a boiling point of 428 K (310 °F) (with decomposition), a freezing point of 158 K (−176 °F), a density of 0.986 g/cm<sup>3</sup>, and an enthalpy of formation of +305 kJ/mol = +73 kcal/mol = +520 cal/g.

Another azidoalkylamine mentioned in the same patents is bis(azidoethyl)methylamine, also known as di(azidoethyl)methylamine,  $(N_3CH_2CH_2)_2NCH_3$ ,  $C_5H_{11}N_7$ , BAZ, with a molecular mass of 169.19 g/mol. It has a boiling point of 431 K (316 °F) (with decomposition), a melting point of 289 K (61 °F), a density of

1.06 g/cm<sup>3</sup>, and an enthalpy of formation of +586 kJ/mol = +140 kcal/mol = +828 cal/g. Di( $\beta$ -azidoethyl)methylamine had been previously described in the literature [312]. It boils at 371–372 K at 0.67 kPa (98–99 °C at 5 mm Hg), and the refractive index is  $n_D^{25} = 1.4824$ .

*N,N*-Diethylaminoethylazide is thermally more stable than DMAZ and can be used as a hypergolic fuel [263].

The enthalpies of formation in the gas phase, vapor pressure, and liquid densities were predicted from theoretical calculations for a group of 13 tertiary amine azides expected to be useful as hypergolic fuels for hypergolic bipropellant combinations, which can provide higher density-specific impulses than MMH but are less toxic and have lower vapor pressures than MMH. The predicted enthalpies of formation were compared to measured data for three similar compounds [313–316]. The calculated density-specific impulses for combinations with RFNA as the oxidizer predicted a 4–34% improvement over RFNA/MMH. One wonders how a bunch of theoretical calculations can lead to a patent at a time when none of the chemical compounds claimed had actually been reduced to practice or fired in a rocket engine.

Thermodynamic properties of a series of azidoamines were studied at the B3LYP/6–311 + G(2df) level of density functional theory [317]. Enthalpies of formation increased quantitatively with increasing temperature as well as the number of azido groups. The azidoamines are highly energetic, with large enthalpies of formation. The detonation performances of the azidoamines were evaluated, and their predicted performances are comparable to those of RDX and HMX. However, they are as sensitive to impact as halogen azides, according to the small potential energy barriers for initiation.

2-(dimethylamino)-1,3-diazidopropane,  $N_3CH_2CH[N(CH_3)_2]CH_2N_3$ , is a hypergolic fuel and can be prepared by methylation of 2-amino-1,3-dihydroxypropane with formaldehyde and formic acid to afford 2-(dimethylamino)-1,3-propanediol, which is then chlorinated and reacted with sodium azide to afford 2-(dimethylamino)-1,3-diazidopropane [318].

It is incomprehensible to an experimental rocket propellant chemist how a U.S. patent could have been awarded to a purely speculative idea that had never been reduced to practice [219]. Those patent examiners who allowed this patent to go through instead of rejecting it must have been either fast asleep or high on drugs. Allowing purely speculative, theoretical wild claims as patentable certainly dilutes the value of other hard-earned patents that have experimental results to prove the realization of their concept.

### 19.3.1 Tris(2-azidoethyl)amine

Tris(2-azidoethyl)amine,  $(N_3CH_2CH_2)_3N$ ,  $C_6H_{12}N_{10}$ , TAEA, is a more energetic azido compound than DMAZ. It contains 62 mass-% nitrogen. It was predicted that a gain of about 7.39% in density impulse can be achieved by the replacement of MMH with

TAEA. It has a refractive index  $n_D^{25}$  of 1.5090, an impact sensitivity of 60–65 in-lb (for comparison, TMETN = 25–30 in-lb), a density of 1.162 g/cm<sup>3</sup>, a freezing point of 254 K = –19 °C, and an enthalpy of formation  $\Delta H_f$  of +887 kJ/mol (+212 kcal/mol). TAEA can be prepared starting with readily available triethanolamine, which is first converted to the trichloride or tritosylate [319, 320]. In the next reaction step, the tris(2-haloethyl)-amine or tris(2-tosylethyl)amine is reacted with an ionic azide such as sodium azide in dipolar aprotic solvents such as dimethylformamide or dimethylsulfoxide, which are used routinely as media for azide ion substitution reactions. Another energetic azide is *n*-butyl(2-azidoethyl)nitramine, which has a refractive index of  $n_D^{24} = 1.4870$ , a freezing point below 195 K (–78 °C), and an impact sensitivity beyond the range of the instrument (> 150 in – lb).

TAEA has been patented as a hypergolic fuel ingredient in mixtures with TMEDA [236, 237]. See also [321].

### 19.3.2 Azidoalkylnitramines

There is a large group of azidoalkylnitramines that are actively evaluated as energetic plasticizers for double-base propellants.

### 19.3.3 Azidopropylamines

Propyleneimine reacts cleanly with HN<sub>3</sub> to give 1-azido-2-aminopropane. This compound can be converted directly to salts, or it can be N-nitrated to give 1-azido-2-propylnitramine, which can be used as the acidic component in energetic salt formation [322]. A similar reaction of hydrazoic acid with ethyleneimine is expected to give 2-azidoethylamine.

### 19.3.4 Azidonitroalkylamines

Azidomethyl bis(fluorodinitroethyl) amine, [FC(NO<sub>2</sub>)<sub>2</sub>CH<sub>2</sub>]<sub>2</sub>NCH<sub>2</sub>N<sub>3</sub>, C<sub>5</sub>H<sub>6</sub>F<sub>2</sub>N<sub>8</sub>O<sub>8</sub>, has a density of 1.638 g/cm<sup>3</sup> at 296 K (23 °C) (for comparison, FEFO = 1.596 g/cm<sup>3</sup>) and an enthalpy of formation of  $\Delta H_f = -138$  kJ/mol = –33 kcal/mol [323, 324].

## 20 C-Nitro- and C-Nitroxy-substituted Alkylamines

The nitro groups in *C*-nitro substituted alkylamines, in particular ethylamines, are usually in  $\beta$  position. Nitro groups in  $\alpha$  position to the amino group result in unstable molecules. The *C*-nitro substituted alkyl groups can form primary, secondary, or tertiary amines. Similar amines were developed with nitroxy groups in the  $\beta$  position of ethylamines, and their nitrate salts were examined.

## 20.1 Nitroethylamines

The ethyl group that is attached to the amino nitrogen can carry one, two, or three nitro groups in the  $\beta$  position. The nitroethylamines thus formed have been evaluated as energetic plasticizers. One of the starting reactants for the synthesis of other energetic compounds is 2,2-dinitroethylamine [325, 326].

An *N*-functionalized strategy, including *N*-amination and *N*-trinitroethylation, was utilized for the synthesis of nitroimidazole-based energetic materials, opening a path to a new family of highly insensitive *N*-aminonitroimidazoles and oxygen-rich *N*-trinitroethylaminonitroimidazoles with good properties [327]. These compounds were fully characterized by IR,  $^1\text{H}$  and  $^{13}\text{C}$  NMR, and elemental analysis, and some high-performance compounds were further confirmed by  $^{15}\text{N}$  NMR as well as single-crystal XRD. *N*-trinitroethylaminonitroimidazoles have favorable densities (1.75–1.84 g/cm<sup>3</sup>), good detonation properties ( $P = 27.6\text{--}35.9$  GPa;  $v_D = 7815\text{--}8659$  m/s), and moderate thermal stabilities (409–445 K = 136–172 °C). These properties are better than some known energetic compounds, such as TNT ( $P = 19.5$  GPa;  $v_D = 6881$  m/s) and TATB ( $P = 31.2$  GPa;  $v_D = 8114$  m/s), and they are comparable to RDX ( $P = 35.0$  GPa;  $v_D = 8762$  m/s).

The preparation of bistrinitroethylnitramine requires bistrinitroethylamine (BTNA) as a precursor. Bistrinitroethylamine can be prepared from potassium trinitromethide and cyclohexamethylenetetramine [328]. The crystals melt at 387 K (114 °C) with decomposition.

Trinitroethanol can be reacted with different moieties through the Mannich reaction, such as ammonia or aliphatic amines as the amine component in order to synthesize the corresponding trinitroethylamine derivatives. Examples include bis(2,2,2-trinitroethyl) amine [329]. Bis(2,2,2-trinitroethyl) amine properties are as follows: DSC  $T_{\text{dec}} = 396.5$  K = 123.4 °C,  $\rho = 1.86$  g/cm<sup>3</sup>,  $\Delta H_f = -77.8$  kJ/mol (calculated),  $\Delta H_f = 0.47$  kJ/g (calculated),  $p_{\text{det}} = 34.2$  GPa (calculated),  $v_{\text{det}} = 8558$  m/s (calculated), impact sensitivity 15 cm, oxygen content 56.0%, oxygen balance +25.6%. The trinitroethanol precursor needed for such syntheses is made by reaction of nitroform with paraformaldehyde [330].

Bis(trinitroethyl)amine, also known as BTNA,  $\text{C}_4\text{H}_5\text{N}_7\text{O}_{12}$ ,  $(\text{O}_2\text{N})_3\text{CCH}_2\text{NHCH}_2\text{C}(\text{NO}_2)_3$ , has a molecular mass of 343.12 g/mol, is a liquid at room temperature, and if frozen solid forms triclinic crystals, space group *Pbca* (no. 61) with  $a = 12.8996(6)$  Å,  $b = 11.7753(5)$  Å,  $c = 16.1577(7)$  Å,  $\alpha = \beta = \gamma = 90^\circ$ ,  $V = 2454$  Å<sup>3</sup>,  $Z = 8$ , and  $\rho_{\text{XRD}} = 1.857$  g/cm<sup>3</sup> [331]. The measured density is 1.881 g/cm<sup>3</sup>, the calculated heat of formation is -138 kJ/kg, and the predicted detonation velocity is 8815 m/s.

2,2-dinitroethylamine can be made by reaction of 1,1,1-trinitroethane with ammonia [326]. A similar reaction with dimethylamine instead of ammonia gives *N,N*-dimethyl-2,2-dinitroethylamine. 2,2-dinitroethylamine is a yellow solid with a melting point of 390 K (117 °C).

Desirable crystal shapes can be achieved by recrystallizing from the best solvent for this task. Bis(2,2,2-trinitroethyl) amine (BTNA) was characterized by elemental analysis, IR spectrometry, and DSC [332]. The crystal morphology and crystallization behavior of BTNA were calculated, and the relationships between the structures of important crystal faces and solvent of crystallization were analyzed. By recrystallizing BTNA from dichloromethane (weak polar solvent), it was found that the crystalloid is more uniform and the aspect ratio is smaller compared with that from water, in accordance with the behavior predicted from theory.

Instead of nitro groups, the alkyl rests in amines can carry nitroxy groups, which form alkyl nitrate esters with an amino group in the alkyl rest. These nitroxyalkylamines can form very energetic nitrate salts [333]. The raw materials for preparation of such nitroxyalkylamines would be the hydroxylalkylamines, which are readily available in industrial quantities.

## 20.2 $\omega$ -Nitroalkylamines

Nitroalkylamines are alkylamines in which the  $C_{>2}$  alkyl groups carry one or more terminal ( $\omega$  position) nitro groups

where R is another alkyl group, typically methyl. By virtue of their exceptional charge delocalization and concomitant reduction in solvation energy, 2-nitroethyl ammonium salts, especially the dinitramide salt, display remarkably low melting points while retaining acceptable stability at room temperature [322].

The nucleophilic Michael addition of nitroform to acrylamide creates 4,4,4-trinitrobutanamide in the first step that can subsequently be converted to 3,3,3-trinitropropylamine and salts containing the trinitropropylammonium cation,  $[(NO_2)_3CCH_2CH_2NH_3]^+X^-$  [334]. For  $X^- = ClO_4^-$ ,  $(NO_2)_2N^-$ ,  $IO_4^-$ , or amino-bistetrazolate, these salts are of interest as propellant ingredients [335].

## 20.3 Fluoronitroalkylamines

Fluorodinitroalkylamines can be more energetic than nitroalkylamines. The fluoro group usually shares space with nitro groups in the  $\beta$  position of ethyl groups. They can be prepared from fluorodinitroethanol or fluorodinitromethane. The enthalpy of formation of bis(2-fluoro-2,2-dinitroethyl)amine (BFDNA) is  $-531 \text{ kJ/mol}$  ( $-126.952 \text{ kcal/mol}$ ) [121].

## 20.4 Nitroalkylnitramines

This book contains a separate section on alkylnitramines, as well as those that carry additional substituents such as nitro or nitroso groups on the alkyl rest. These compounds are mostly discussed in the section on nitramines, but they also carry some resemblance to nitroalkylamines. There may be some overlap between these sections.

Bis(2,2,2-trinitroethyl)nitroamine, CAS RN [19836-28-3], has been proposed as an ingredient in smokeless propellants [336]. Bis(2,2-dinitroethyl-*N*-nitro)ethylenediamine,

forms salts with organic bases exhibiting favorable physical properties, good detonation properties, and relatively low impact sensitivities. They can be synthesized in high yield by direct reactions of bis(2,2-dinitroethyl-*N*-nitro)ethylenediamine with organic bases [337]. The resulting salts were fully characterized by multi-nuclear NMR spectroscopy ( $^1\text{H}$  and  $^{13}\text{C}$ ), IR vibrational spectroscopy, DSC, and elemental analysis. Thermal decomposition kinetics and several thermodynamic parameters of some salts were obtained under non-isothermal conditions by DSC. The densities of the energetic salts paired with organic cations were in the range of 1.60–1.89 g/cm<sup>3</sup> as measured with a gas pycnometer. Based on the measured densities and calculated heats of formation, detonation pressures and velocities were calculated using the Explo 5.05 program and were predicted to be 23.6–44.8 GPa and 7790–9583 m/s, respectively, which makes them potentially useful as energetic materials.

## 20.5 Nitroalkylhydrazines

Due to similarity between alkylamines and alkylhydrazines, and between nitroalkylamines and nitroalkylhydrazines, a short reference to nitroalkylhydrazines is included here. It is unusual to have an oxidizing group like the nitro group and a reducing group like the hydrazino group in the same molecule. One would not expect good thermal stability from such an arrangement.

A study has been made of the IR spectra of *N*- $\alpha$ -polynitroalkylhydrazine derivatives, and band assignments were made for stretching vibrations in the NH, CO, and NO<sub>2</sub> groups [338]. Integral intensities for NO<sub>2</sub> anti-symmetrical stretching absorption bands are additive. Splitting of these bands is characteristic of nitro compounds containing a hydrazine group in the  $\alpha$ -position with respect to the nitro group. It has been shown that intermolecular hydrogen bonding exists in the *N*- $\alpha$ -polynitro-alkylhydrazines, both in the crystalline state and in concentrated solutions.

## 20.6 $\beta$ -Nitroxyethyl Amines

Nitroxy-functionalized cations and their nitrate salts were synthesized as potential halogen-free oxidizers for solid propellants, and their thermal stability was examined [339, 340]. It was expected that quaternized nitroxyalkylammonium nitrates would be thermally more stable than their primary ammonium salt counterparts. There was a hypothesis that the thermal stabilities of salts with nitroxy-functionalized cations might correlate with the length(s) of their O—N bond(s). Gas-phase proton affinity, heats of sublimation, and lattice enthalpies were calculated. The salts prepared and modeled by quantum mechanical computational methods included 2-nitroxy-*N,N,N*-trimethylethanammonium nitrate, 2-nitroxy-*N*-(2-nitroxyethyl)-*N,N*-dimethylethanammonium nitrate, 2-nitroxy-*N,N*-bis(2-nitroxyethyl)-*N*-methylethanammonium nitrate, and 1-(2-nitroxyethyl)-2,3-dimethyl-5-nitroimidazolium nitrate. The thermal decomposition temperatures were in the range of 403–426 K (130–153 °C), substantially lower than that of AP, which they were intended to replace. The  $\Delta G_{298}$  results indicated that it is highly unlikely that any nitrate salt with a cation having more than two  $\text{NO}_x$  groups will be thermally stable for 24 h at 348 K (75 °C).

## 21 C-Cyano-Substituted Amines

The introduction of cyano groups into alkylamines increases the enthalpy of combustion and the performance as rocket fuels. A typical example would be 2-cyanoethylamine, 3-aminopropionitrile,  $\text{C}_3\text{H}_6\text{N}_2$ , CAS RN [151-18-8]

which can be made by cyanoethylation of ammonia and has been studied for its IR spectrum [341], but it has not yet been tested as a rocket fuel. The gas-phase enthalpy of formation is 89.75 kJ/mol. It boils at 352–354 K at a reduced pressure of 0.021 bar. Bis-(2-cyanoethyl) amine

can be made by reaction of acrylonitrile with ammonia [342]. Bis-(2-cyanoethyl) amine could be used as a rocket fuel.

Continuing the reaction with an excess of acrylonitrile would eventually lead to tris(2-cyanoethyl) amine,  $\text{C}_9\text{H}_{12}\text{N}_4$ , which should also make a good rocket fuel, although it is a solid with a melting point of 326–327 K (53–54 °C) [343].

Bis-(2-cyanoethyl) amine can be reacted with oxiridines (alkoxides) to form energetic fuels to be used as building blocks in energetic binders for solid propellants [344].

## 22 Hydrazido-Substituted Amines

The introduction of a hydrazine group into an alkylamine results in fuel molecules with properties somewhere between those of alkylamines and alkylhydrazines, similar to physical mixtures of the two. Typical examples would be

|                                                  |                                                              |
|--------------------------------------------------|--------------------------------------------------------------|
| $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHNH}_2$ | $(\text{H}_3\text{C})_2\text{NCH}_2\text{CH}_2\text{NHNH}_2$ |
| 2-aminoethylhydrazine                            | <i>N</i> -dimethylaminoethylhydrazine                        |
| 2-hydrazinoethylamine                            | 2-hydrazinoethyldimethylamine                                |
| 1,2,5-triazapentane                              | 5,5-dimethyl-1,2,5-triazapentane                             |

## 23 C-Hydroxy-Substituted Amines

Hydroxy groups can be introduced into alkylamines either at the carbon atoms (discussed in this section) or at the nitrogen atom (discussed in *Encyclopedia of Oxidizers*, chapter “Hydroxylammonium Salts,” under substituted hydroxylamines). These compounds are structural isomers with identical gross formulas.

The most important *C*-hydroxyalkylamines are those derived from ethylamine, diethylamine, and triethylamine by replacing the ethyl group(s) with 2-hydroxyethyl group(s). These amines are prepared in large quantities by reaction of ammonia with ethylene oxide, and the process typically produces mixtures of the three amines that must be separated by distillation. The identifier *C*- for substitution on the alkyl group will be omitted in further discussion of these chemicals in the following sections. Because hydroxyl substitution in the alpha position of ethylamine results in unstable molecules, it is always assumed that the substitution was made in the beta position when referring to hydroxyethylamine, even if the 2- designator is missing.

Hydroxyethylamine, bis(2-hydroxyethyl)amine, and tri(2-hydroxyethyl)amine are available in large quantities and have found various industrial and cosmetic uses. They are weak bases and form salts with most acids. Because of the excellent water solubility, nitrates of any of these three amines have been considered as fuels for HAN-based monopropellants. In particular, the nitrate salt of tri(2-hydroxyethyl)amine, trihydroxyethylammonium nitrate (TEAN), has been extensively investigated and is relatively well characterized. Because these salts are readily water soluble, un-deroxidized, and compatible with HAN, the properties of their parent amines have been included in this encyclopedia.

### 23.1 Ethanolamine

Ethanolamine, also known as monoethanolamine, 2-hydroxyethylamine,  $\text{HOCH}_2\text{CH}_2\text{NH}_2$ ,  $\text{C}_2\text{H}_7\text{ON}$ , CAS RN [141-43-5], forms as one of several products in the hydroxyethylation of ammonia by reaction with ethylene oxide. Ethanolamine is a potential contaminant of diethanolamine and triethanolamine. It is more likely to be nitrosated from atmospheric  $\text{NO}_x$  than triethanolamine; therefore, its presence as a contaminant in triethanolamine is undesirable in pharmaceutical or cosmetic preparations. Ethanolamine would be a better rocket fuel than ethanol because it is more reactive, but it contains less hydrogen (11.55% H vs. 13.12% H in EtOH).

#### 23.1.1 Physical Properties of Ethanolamine

Physical properties of ethanolamine are listed in Table 57.

**Table 57:** Physical properties of ethanolamine.

| Property                        | SI units                 | Other units                   | References |
|---------------------------------|--------------------------|-------------------------------|------------|
| Molecular mass                  | 61.0831 g/mol            | 16.37 mol/kg                  | [29]       |
| Boiling point                   | 443.2 K                  | 170.1 °C                      | [29]       |
| Freezing point                  | 283.45 K                 | +10.3 °C                      | [29]       |
| Density at 298 K                | 1.0127 g/cm <sup>3</sup> | 63.22 lb/ft <sup>3</sup>      |            |
| Refractive index, $n_D^{20}$    | 1.4539                   | —                             |            |
| Enthalpy of formation, liquid   | −507.5 kJ/mol            | −121.3 kcal/mol               | [29]       |
|                                 | −507 kJ/mol              | −1986 cal/g = −121.3 kcal/mol | [27]       |
| Enthalpy of vaporization at NBP | 58 ± 3 kJ/mol            | 13.9 ± 0.7 kcal/mol           | [29]       |

The vapor pressure of ethanolamine in the range 338.6–444.1 K can be calculated from the equation

$$\log P = 4.29252 - [1408.873/(T - 116.093)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

#### 23.1.2 Chemical Properties of Ethanolamine

Ethanolamine forms salts with many strong acids.

##### 23.1.2.1 Ethanolammonium Nitrate

Physical properties of 2-hydroxyethylammonium nitrate are listed in Table 58. The thermal stability of 2-hydroxyethylammonium nitrate was measured by thermal analysis [345].

**Table 58:** Physical properties of 2-hydroxyethylammonium nitrate.

| Property              | SI units               | Other units     | References |
|-----------------------|------------------------|-----------------|------------|
| Molecular mass        | 124.096 g/mol          | 8.058 mol/kg    |            |
| Oxygen balance        | -51.5%                 |                 |            |
| Melting point         | 323 K                  | 50 °C           |            |
| Density               | 1.33 g/cm <sup>3</sup> |                 |            |
| Enthalpy of formation | -576 kJ/mol            | -137.6 kcal/mol | [17]       |

If ethanolammonium nitrate is treated in strong nitrating acid, it will form a nitrate ester with the hydroxyl group, and the resulting energetic material is called ethanolamine dinitrate:  $\text{O}_2\text{NO}-\text{CH}_2-\text{CH}_2-\text{NH}_3^+\text{NO}_3^-$ ,  $\text{C}_2\text{H}_7\text{N}_3\text{O}_6$  with a molecular mass of 169 g/mol. Its enthalpy of formation was predicted to be  $-2.27 \text{ kJ/g} = -387 \text{ kJ/mol}$ , but measurements gave an enthalpy of formation of  $-2.77 \text{ kJ/g} = -468 \text{ kJ/mol}$  [59]. There was concern that a similar nitrate ester formation reaction could take place in concentrated HAN solutions when the nitrate salts of hydroxyethylamine or trihydroxyethylamine are used as the fuels in HAN-based monopropellants. The nitrate ester nitrate salt would be more sensitive than the normal nitrate salt.

#### 23.1.2.2 Toxicity of Ethanolammonium Nitrate

The liver enzyme toxicity of a number of water-soluble oxidizer and fuel ingredients for non-toxic monopropellants intended as replacements for monopropellant hydrazine was tested *in vitro* using rat hepatocytes [346]. *In vitro* rat hepatocyte toxicity and bacteria (*Salmonella*) genotoxicity assays were performed on 13 high-energy chemicals that were candidates for potential replacement monopropellants for hydrazine. The chemicals were primarily hydrazine derivatives and amino compounds. Ethanolammonium nitrate is one of the less toxic compounds in this group. It is neither genotoxic nor mutagenic.

#### 23.1.2.3 Ethanolammonium Dinitramide

Ethanolammonium dinitramide, ethanolamine dinitramide,  $[\text{HOCH}_2\text{CH}_2\text{NH}_3^+]\text{[N(NO}_2)_2^-]$ , melts at 310–312 K (37–39 °C) [97]. The enthalpy of formation of this salt was not measured but was extrapolated from similar salts as  $-335 \text{ kJ/mol}$  (calculated) ( $-80 \text{ kcal/mol}$ ).

#### 23.1.3 Applications of Ethanolamine

Mixtures of ethanolamine and ethanol can be hypergolized with hydrogen peroxide by adding soluble catalysts. A solution of 1% copper(II) chloride in ethanolamine was found to rapidly ignite with 90% hydrogen peroxide [347, 348].

A mixture of ethanol and ethanolamine can be made hypergolic with hydrogen peroxide, featuring low toxicity and high density-specific impulse [349]. Several different catalysts were dissolved in ethanolamine. Among the catalytic materials tested, copper nitrate achieved the shortest ignition delay. The results showed that an optimized fuel composition with 61 mass-% ethanolamine, 30% ethanol, and 9% hydrated copper nitrate yielded a minimum ignition delay of 15.7 ms.

Ethanolamine with dissolved metal salt catalysts or a suspension of sodium borohydride gave a very short ignition delay in open-cup drop tests with hydrogen peroxide [350, 351].

Other laboratories started looking into how to improve the handling safety of ethanolamine as a rocket propellant by gelling it with polyvinylpyrrolidone and fumed silica [352–354]. This fuel can be hypergolic with hydrogen peroxide as the oxidizer, constituting a less toxic but also hypergolic replacement for dinitrogen tetroxide (NTO)/MMH [355].

## 23.2 Diethanolamine

Diethanolamine, also known as bis(2-hydroxyethyl)amine, 2,2'-iminodiethanol,  $(\text{HOCH}_2\text{CH}_2)_2\text{NH}$ ,  $\text{C}_4\text{H}_{11}\text{O}_2\text{N}$ , CAS RN [111-42-2], forms as a byproduct in the hydroxyethylation of ammonia by reaction with ethylene oxide if the intended end product is triethanolamine. Diethanolamine is a potential contaminant of triethanolamine. It is more likely to be nitrosated from atmospheric  $\text{NO}_x$  than triethanolamine; therefore, its presence as a contaminant in triethanolamine is undesirable in pharmaceutical and cosmetic preparations. Both are used as moisturizers in cosmetic preparations and as sorbents to remove acidic gases from natural gas or industrial gas streams.

### 23.2.1 Physical Properties of Diethanolamine

Diethanolamine forms low-melting colorless prismatic crystals that melt at 301 K and boil at 544 K (268 °C). Physical properties of diethanolamine are listed in Table 59.

The vapor pressure of diethanolamine in the range 467–514 K can be calculated from the equation

$$\log P = 5.19445 - [2273.949 / (T - 103.362)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

### 23.2.2 Chemical Properties of Diethanolamine

Diethanolamine reacts with  $\text{NO}_x$  from the environment or from combustion products to form *N*-nitrosodiethanolamine, a proven human carcinogen. The formation of this compound must be avoided if contaminated triethanolammonium nitrate is used as a fuel in HAN-based monopropellants. There are numerous publications on the car-

**Table 59:** Physical properties of diethanolamine.

| Property                     | SI units                 | Other units              | References |
|------------------------------|--------------------------|--------------------------|------------|
| Molecular mass               | 105.1356                 | 9.511 mol/kg             | [29]       |
| Boiling point at 101 kPa     | 544.2 K                  | 268 °C                   | [29]       |
| Boiling point at 20 kPa      | 490.2 K                  | 217.1 °C                 | [29]       |
| Melting point                | 301.1 K                  | 28 °C                    | [29]       |
| Density at 298 K             | 1.0935 g/cm <sup>3</sup> | 68.26 lb/ft <sup>3</sup> |            |
| Refractive index $n_D^{20}$  | 1.4776                   | —                        |            |
| Enthalpy of formation, solid | -493.8 ± 2.6 kJ/mol      | -118 ± 0.6 kcal/mol      | [29]       |

cinogenicity of *N*-nitrosodiethanolamine (CAS RN 1116-54-7), which was also found in some aged cosmetic preparations and in tobacco smoke (one of the growth retardants applied to tobacco plants is a salt of diethanolamine). Most of these publications date to the 1980s, when this carcinogen was first discovered. It is possible that similar hazardous compounds form during partial combustion of the nitrate salts of (mono-, di-, tri-)ethanolamines in rocket engines or liquid propellant gun breeches.

Diethanolamine forms salts with strong acids. Diethanolammonium dinitramide,  $[(\text{HOCH}_2\text{CH}_2)_2\text{NH}_2^+][\text{N}(\text{NO}_2)_2^-]$ , melts at 348–351 K (75–78 °C) [97].

### 23.3 Triethanolamine

Triethanolamine, also known as tri(2-hydroxyethyl)amine,  $(\text{HOCH}_2\text{CH}_2)_3\text{N}$ ,  $\text{C}_6\text{H}_{15}\text{NO}_3$ , nitrilotriethanol, 2,2',2''-nitrilotri(ethan-1-ol), triethylolamine, TEA, 2-[bis-(2-hydroxyethyl)amino]ethanol, CAS RN [102-71-6], is a widely used industrial intermediate that has not been used as a rocket propellant in the form of its free base, but it once found extensive use in the form of its nitrate salt triethanolammonium nitrate (TEAN) in liquid gun propellants and a few rocket propellants. However, its use has been discontinued (see *Encyclopedia of Monopropellants*, chapter “Hydroxylammonium Nitrate-based Monopropellants”). Other names for this compound are 2,2',2''-nitrilotriethanol, tri(2-hydroxyethyl)amine, tris(2-hydroxyethyl)amine, 2,2',2''-trihydroxy-triethylamine, trihydroxyethylamine, and triethylolamine.

Triethanolamine, the free amine, is widely used as a moisturizer in cosmetic products. There is a long history of use of this chemical (the free amine), and its toxicity has been well researched. There is concern about contamination by diethanolamine in triethanolamine because the diethanolamine is likely to form nitrosamines with  $\text{NO}_x$  in the polluted atmosphere.

The structural formula of triethanolamine is illustrated in Figure 10.

It is a derivative of triethylamine (a frequently used hypergolic fuel), with hydroxyl groups attached at the ends of each of the three ethyl groups. These three hydroxyl groups raise the boiling point of the compound substantially, from 362.6 to 608 K (de-

**Figure 10:** Molecular structure of triethanolamine

composition). One might also look at it as a derivative of ethanol, another widely used rocket fuel, by combining three ethanols via a nitrogen atom. Looking at it in this way, triethanolamine has relationships to rocket fuels “in its genes” since both ammonia and ethanol have been used as rocket fuels.

We list triethanolamine here mostly because it is an intermediate in the preparation of other fuels and because its nitrate salt has been widely used in liquid gun propellants and, to a lesser extent, even in some experimental rocket propellants.

### 23.3.1 Production of Triethanolamine

Triethanolamine is produced by the reaction of ethylene oxide with ammonia. Monoethanolamine and diethanolamine are formed as undesirable byproducts.

### 23.3.2 Physical Properties of Triethanolamine

Physical properties of triethanolamine are listed in Table 60.

**Table 60:** Physical properties of triethanolamine.

| Property                      | SI units                              | Other units                               | References |
|-------------------------------|---------------------------------------|-------------------------------------------|------------|
| Molecular mass                | 149.1882 g/mol                        | 6.7029 mol/kg                             | [29]       |
| Boiling point at 101 kPa      | 608 K (dec.)                          | 335 °C (dec.)                             | [29]       |
| Boiling point at 0.7 kPa      | 464.7 K                               | 191.6 °C                                  | [29]       |
| Melting point                 | 294.72 K                              | 21.6 °C                                   | [29]       |
| Density at 298 K              | 1.1217 g/cm <sup>3</sup>              | 70.03 lb/ft <sup>3</sup>                  |            |
| Refractive index $n_D^{20}$   | 1.4850                                | —                                         |            |
| Heat capacity at 298 K        | 2.6 J g <sup>-1</sup> K <sup>-1</sup> | 0.62 cal g <sup>-1</sup> °C <sup>-1</sup> |            |
| Enthalpy of formation, liquid | -664.2 ± 1.5 kJ/mol                   | -158.7 ± 0.4 kcal/mol                     | [29]       |

The vapor pressure of triethanolamine in the range 525.9–578.8 K (252.7–305.7 °C) can be calculated from the equation

$$\log P = 7.19251 - [4543.902/(T + 24.749)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

### 23.3.3 Chemical Properties of Triethanolamine

Triethanolamine is a weak base with a  $pK_a$  of 7.74. It forms salts with strong acids. The nitrate salt of TEA, called TEAN, has been widely used as the fuel in HAN-based liquid gun propellants. There was a question of whether strongly acidic conditions in TEAN in the presence of excess nitric acid would result in partial esterification of one or more of the hydroxyl groups in TEA, resulting in a more sensitive alkyl nitrate amine nitrate. This suspicion has not been proven.

### 23.3.4 Hazard Properties of Triethanolamine

The flash point of triethanolamine in air is at 452 K (179 °C = 354 °F). The auto-ignition temperature of triethanolamine in air is at 598 K (325 °C = 617 °F).

### 23.3.5 Toxicity of Triethanolamine

Triethanolamine is not used as a rocket propellant as such, but it has been used in the form of its nitrate salt. The toxicity of the two compounds, the free base and its nitrate salt, would be very similar, except the nitrate salt is more toxic due to the toxicity of the nitrate ion.

Triethanolamine, the free base precursor to triethanolammonium nitrate, has been around for a long time. It is widely used as a moisturizer in cosmetic formulations and to wash carbon dioxide and/or hydrogen sulfide from industrial waste gases and natural gas. It is also used in cutting (cooling) fluids and oil emulsions when machining or drilling metal parts. It has a perfect use history, and no adverse effects have been reported during the many decades that it has been in use. The main toxicity concern arises from a contaminant in triethanolamine, the incompletely hydroxyethylated diethanolamine, which readily picks up  $\text{NO}_x$  from the environment to form toxic nitrosamines. The TLV-TWA for triethanolamine is 5 mg/m<sup>3</sup>.

Although TEAN is no longer anticipated to be widely used as a gun or rocket propellant ingredient, we have assembled a short list of publications on the toxicity of triethanolamine and the other ethanolamines: [356–360].

### 23.3.6 Salts of Triethanolamine

Hydroxyethylamine, di(2-hydroxyethyl)amine and tris(2-hydroxyethylamine), are available in large quantities and have found various industrial and cosmetic uses. They are weak bases and form salts with most acids. Because of the excellent water

solubility, nitrates of any of these three amines have been considered as fuels for HAN-based monopropellants. In particular, the nitrate salt of tri(2-hydroxyethyl)-amine, trihydroxyethylammonium nitrate (triethanolammonium nitrate, TEAN) has been extensively investigated and it is relatively well characterized.

#### 23.3.6.1 Triethanolammonium Nitrate

Triethanolammonium nitrate, also known as TEAN,  $[(\text{HOCH}_2\text{CH}_2)_3\text{NH}^+][\text{NO}_3^-]$ ,  $\text{C}_6\text{H}_{16}\text{N}_2\text{O}_6$ , CAS RN [27096-29-3], with a molecular mass of 212.201 g/mol, an oxygen balance of -105.6%, and a nitrogen content of 13.2%N, is the nitrate salt of triethanolamine. TEAN is one of the few amine nitrates that saw widespread application during the development of regenerative liquid propellant guns in the 1980s and 1990s. It has since fallen into oblivion. At one point, the industry was prepared to gear up for large-scale production of TEAN and other ingredients [361], but the demand never arose, and the predictions of future demand for this material were overly optimistic. TEAN manufacturing facilities have been closed and scrapped. It is unlikely that it will ever again find widespread application in HAN-based monopropellants. Nevertheless, some of its properties are summarized here.

#### 23.3.6.2 Preparation of Triethanolammonium Nitrate

TEAN slush is made by neutralizing triethanolamine with dilute nitric acid. The 80% TEAN solution must be stored warm to prevent crystallization. It is not necessary to recrystallize the salt and remove all water from the solution, but the propellant can be formulated from highly concentrated 80 mass-% TEAN solutions with accurately known water content. That is acceptable for making XM-46 as long as the water brought in with the HAN and the water brought in with the TEAN add up to 20%. The heat of solution of the two liquids is negative. This small enthalpy change is often ignored when calculating the theoretical performance of HAN-based propellants.

The most useful method in terms of both assay and organic impurity detection for quality control of the TEAN thus produced has been NMR spectroscopy [362, 363].

The heat of reaction of neutralization of TEA with  $\text{HNO}_3$  is  $-57.7 \text{ kJ/mol} = -13.8 \text{ kcal/mol}$ . If the reacting mixture gets too hot, unwanted side reactions may occur. It has been noted that the undesirable formation of *N*-nitrosodiethanolamine during the neutralization of TEA can be avoided if the temperature is kept below 277 K (4°C), the TEA concentration used is at least 97%, and the amine is added to the acid, never the other way around [364]. See also [365].

#### 23.3.6.3 Physical Properties of Triethanolammonium Nitrate

##### Melting Point of TEAN Crystals

Based on DSC data, the melting point of TEAN is 353 K (80°C). Other sources report a melting point of 357 K (84°C).

### Freezing Point of TEAN Solutions

The freezing and melting points of TEAN solutions with 10 to 79 mass-% TEAN were measured in gold DSC pans at temperatures down to 205 K [366]. All TEAN solutions showed supercooling effects, in particular a solution with 74.9% TEAN. Many heating curves showed two endothermic peaks, with the second peak being attributed to free water. It was suspected that the reason for two peaks is that some of the TEAN recrystallizes during melting or pre-melting. Figure 11 shows the phase diagram for TEAN/H<sub>2</sub>O, where the eutectic is close to 55–60% TEAN at about 260 K. The solid line is the theoretical freezing point assuming the dissociation into two ions. The diamond and square symbols are measured melting-point values where the higher melting point and the eutectic point were employed. The heat of fusion of TEAN can be calculated from the melting-point suppression and comes out to be 27.89 kJ/mol (6.665 kcal/mol) compared to that of water, 6.00 kJ/mol (1.434 kcal/mol). Similar measurements were made for HAN and LP-1845.

**Figure 11:** Melting temperature of TEAN solutions. (Republished and modified from [366], with permission of ©1991 Springer Nature BV; permission conveyed through Copyright Clearance Center Inc.)

The thermal behavior of the binary system of TEAN/H<sub>2</sub>O at low temperature has been investigated using DSC, and the phase diagrams of TX (a correlation of the liquidus temperature with the composition) and HX (a correlation of the apparent heat of fusion with the composition) for the system were constructed [367]. It was found that the TEAN/H<sub>2</sub>O system is a simple binary system, whose eutectic temperature is 256.9 K (−16.2°C).

### Density of TEAN Crystals

Based on XRD data, the computed density of crystalline TEAN is  $1.393 \text{ g/cm}^3$ . Other sources give a crystal density of  $1.44 \text{ g/cm}^3$ . Extrapolating from the density of TEAN solutions to 100% TEAN gives a density of  $1.328 \text{ g/cm}^3$ , which is closer to that of molten TEAN than to that of crystalline TEAN [19].

### Density of TEAN Solutions

The density of aqueous TEAN solutions as a function of TEAN concentration at 294 K (21 °C) can be calculated from

$$\rho = 0.985896 + 0.003424X$$

or

$$\rho = 1.003784 + 0.0546873M$$

where  $\rho$  is the density in  $\text{g/cm}^3$ ,  $X$  is the TEAN concentration in mass-%, and  $M$  is the TEAN concentration in mol/L [19].

The apparent molar volume of solutions is the sum of the partial molar volume of the solute and that of the solvent (water). A good correlation can be obtained by plotting the partial molar volume against a concentration parameter  $\chi$

$$\chi = \frac{\sqrt{X}}{1 + \sqrt{X}}$$

where  $X$  is the mole fraction of TEAN. This correlation was used at Olin Chemicals for calculating the densities of HAN and TEAN solutions, as well as the densities of XM46 formulations with excess nitric acid [368]. The slope of the linear function ( $X$  coefficient) shown in Figure 12 is 27.8225. The intercept at infinite dilution is at  $149.176 \text{ cm}^3/\text{mol}$ . The same method was also used for AN solutions.

**Figure 12:** Apparent molar volume of TEAN at 293 K (20 °C) as a function of concentration parameter  $\chi$ . (Reproduced and modified from [368], based on data from [19].)

### Solubility of Triethanolammonium Nitrate

The solubility of TEAN in water at 298 K is 90%.

### Velocity of Sound and Molecular Relaxation in Triethanolammonium Nitrate Solutions

Triethanolammonium and nitrate ions in concentrated TEAN solutions are surrounded by a sphere of hydration. The relaxation in the rate of exchange of water molecules in the hydration sphere in TEAN solutions was measured by Rayleigh-Brillouin spectra at atmospheric pressure over a temperature range from 205 to 298 K [369, 370]. Similar measurements were performed on HAN solutions. See also [371–373].

### Thermodynamic Properties of Triethanolammonium Nitrate

The heat of fusion of TEAN is 27.9 kJ/mol. The entropy of fusion is  $78.2 \text{ J K}^{-1} \text{ mol}^{-1}$  [374]. The enthalpy of formation of TEAN is  $-966 \text{ kJ/mol}$  ( $-231 \text{ kcal/mol} = -1089 \text{ cal/g}$ ).

### Molecular Structure of Triethanolammonium Nitrate

Triethanolammonium nitrate exhibits rather unusual liquid properties that have been attributed to its being a “molten eutectic” of fused salts rather than a normal aqueous solution. A hydrogen-bonded liquid structure for eutectic LP1846 was proposed previously, based on the known structures of neat HAN and water and a best-guess estimate of the TEAN structure. To verify this estimate, the molecular structure of neat TEAN was determined [375]. This investigation revealed that TEAN has very unusual and interesting bifurcated intermolecular and trifurcated intramolecular hydrogen bonding configurations within the crystal. If these hydrogen bonding configurations are retained in aqueous solution, they could be responsible in some part for the observed unusual liquid properties of liquid propellant XM46.

TEAN crystallizes in the centrosymmetric monoclinic space group  $P2_1/c$ , with  $a = 6.592$ ,  $b = 16.358$ ,  $c = 9.3850 \text{ Å}$ , and  $\beta = 90.87^\circ$ . Based on four formula weights of TEAN per unit cell, the computed density is  $1.393 \text{ g/cm}^3$ . The TEAN asymmetric unit contains one TEA<sup>+</sup> cation and one nitrate anion. The TEA<sup>+</sup> cation contains six non-equivalent carbon atoms, one nitrogen atom, and 12 non-equivalent hydrogen atoms. The TEA<sup>+</sup> cation is combined with the nitrate anion which contains one nitrogen atom and three non-equivalent oxygen atoms. In this structure, each ion is surrounded by four oppositely charged ions. In addition to electrostatic forces, the structure is held together by a 3D network of hydrogen bonds between cations and between cations and anions. All of the hydroxyl hydrogen atoms of the cation and two of the nitrate oxygen atoms are involved in this interionic hydrogen-bond network. In the cation–anion linkage of this network, two of the hydroxyl groups from the TEA<sup>+</sup> cation form three hydrogen bonds with two oxygen atoms of the nitrate anion. One of the hydrogen bonds is formed between a hydroxyl hydrogen atom and an oxygen atom of the nitrate ion within the same asymmetric unit. The second hydroxyl hydrogen atom forms an asymmetrically

bifurcated hydrogen bond between two oxygen atoms of a nitrate. Not much is known about the structure of TEAN in solution.

#### 23.3.6.4 Thermal Stability of Triethanolammonium Nitrate

The thermal decomposition of TEAN begins below the melting point. Some decomposition products can already be detected in the gas space above the solid starting at 373 K (100 °C). Decomposition products include  $\text{N}_2\text{O}$ , acetaldehyde, and  $\text{CO}_2$ .

Measurements were made by FTIR spectroscopy to identify the thermal decomposition products of solid TEAN at atmospheric pressure in a nitrogen environment [376]. Solid TEAN produced major IR-active decomposition species such as  $\text{H}_2\text{O}$ ,  $\text{NO}$ , and  $\text{CO}_2$  over the temperature range of 533 to 613 K (260 to 340 °C).  $\text{CO}$ ,  $\text{N}_2\text{O}$ , and  $\text{NO}_2$  were also detected in small concentrations. It was also found that solid TEAN started to decompose near 533 K (260 °C), much higher than its melting temperature of 354 K (81 °C).

The TEAN DSC curve at ambient pressure (Figure 13) displays only two peaks: a sharp endotherm with an onset temperature at 353 K (80 °C) and a broad exotherm with an onset temperature at 524 K (251 °C). The sharp endotherm is caused by the melting of TEAN.

**Figure 13:** Differential scanning calorimetry analysis of TEAN. (Reproduced and modified from [375].)

#### 23.3.6.5 Combustion of TEAN

Work on the reaction kinetics of TEAN by itself (without added oxidizer) was done in support of combustion studies with XM46. It appears that TEAN is less reactive

than HAN. It lags in the sequence of combustion of constituents of the XM46 propellant mixture. Particles of molten TEAN burn in an atmosphere of HAN decomposition products, mostly nitrous oxide. A study of this process was therefore isolated from the initial HAN decomposition by burning TEAN in pure  $N_2O$ . This can be done in a shock tube where the temperature of the gas can be raised suddenly and exactly. A shock tube was used to measure the activation energy of TEAN powder ignition in oxygen/argon or nitrous oxide/argon environments [377–380]. The activation energy of solid TEAN was very close to that reported for aqueous HAN. It was suggested that the measured activation energy ( $40 \text{ kJ/mol} = 9.6 \text{ kcal/mol}$  in nitrous oxide/argon) was largely due to the melting of TEAN; that is, the melting might be the rate-limiting step, inasmuch as the heat of fusion for TEAN is  $149 \text{ J/g}$  or  $7.55 \text{ kcal/mol}$ . The activation energy for the ignition process is  $86.6 \text{ kJ/mol}$  ( $20.7 \text{ kcal/mol}$ ) in  $N_2O$  and  $71.1 \text{ kJ/mol}$  ( $17.0 \text{ kcal/mol}$ ) in oxygen.

## 24 Dimethylaminoethanol

Dimethylaminoethanol, also known as ethanoldimethylamine, dimethylethanolamine, *N,N*-dimethylaminoethanol,  $\text{HOCH}_2\text{CH}_2\text{N}(\text{CH}_3)_2$ , DMEA, CAS RN [108-01-0], is the product of reaction of dimethylamine with ethylene oxide. Dimethylaminoethanol is hypergolic with WFNA or RFNA but not with NTO [381]. The ignition-delay times of dimethylaminoethanol with WFNA or RFNA are 26 and 42 ms, respectively.

### 24.1 Physical Properties of Dimethylaminoethanol

The density of dimethylaminoethanol is higher than that of MMH and UDMH. The viscosity of dimethylaminoethanol is relatively high, which causes more pressure drop and requires higher feed pressure or more pumping work. Since dimethylaminoethanol has a higher flash point than other fuels used as hypergolic rocket propellants, it would be safer to handle. Table 61 gives a list of physical properties of dimethylaminoethanol in comparison to other rocket fuels.

### 24.2 Diethylaminoethanol

Diethylaminoethanol, ethanoldiethylamine, diethylethanolamine, diethylaminoethanol,  $\text{HOCH}_2\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2$ , is the product of reaction of diethylamine with ethylene oxide. Its boiling point is higher than that of triethylamine, and it will reduce the vapor pressure of the mixture. Mixtures of diethylethanolamine with triethylamine (also filled with carbon powder and gelled with hydroxypropyl cellulose) have been patented as hypergolic fuels [382].

Table 61: Physical properties of dimethyaminoethanol in comparison to other rocket fuels.

| Property                                                                                        | Liquid fuels             |                                          |                                            |                                       |                                                      |                                                       |                                         |

### 24.3 1,3-Dihydroxy-2-amino-propane (Serinol)

If the hydroxyl group on the central carbon atom in glycerol is replaced by an amino group, one obtains a low-vapor-pressure amine ( $\text{C}_3\text{H}_9\text{N}_1\text{O}_2$ , 2-aminoglycerol, serinol, naturally occurring and related to the amino acid serine) that can form salts that have ionic liquid properties and very low melting points [383]. The properties of some of these salts with oxidizing anions are summarized in Table 62. The crystal structures of these salts were identified using XRD.

There is also an isomer of serinol, 1,2-dihydroxy-3-amino-propane (3-amino-1,2-propanediol, 1-aminoglycerol, chiral) that has similar properties, but its salts have even lower melting points. Two of these salts are included in the table below.

**Table 62:** Properties of dihydroxy-amino-propane salts.

| Anion                               | Melting point |       | Onset of decomposition |     | Impact sensitivity | Friction sensitivity |       |

## 25 Nitrate Esters of Hydroxyethylamines

It has been suspected that under strongly acidic conditions and in the presence of free nitric acid, some of the terminal hydroxyl groups of TEAN might become esterized and form nitrate esters. Such chemical changes could occur in propellant blends with TEAN and HAN, but they may occur only very slowly. The nitrate esters of mono-, di-, and trihydroxyethylamine and their nitrate salts have been prepared by other routes, not only to have them available as reference compounds but also to evaluate them as energetic additives. Some of these compounds lack thermal stability.

A group of nitroxyalkyl-functionalized ammonium salts, including *N*-(2-nitroxyethyl)-*N,N,N*-trimethylammonium nitrate, *N,N*-bis(2-nitroxyethyl)-*N,N*-dimethylammonium nitrate, *N,N,N*-tri(2-nitroxyethyl)-*N*-methylammonium nitrate, and *N*-(2,3-dinitroxypropyl)-*N*-(2-nitroxyethyl)-*N,N*-dimethylammonium nitrate, exhibited surprising thermal and hydrolytic stability [384].

# Alkanes

## Introduction

*Encyclopedia of Liquid Fuels* contains eight chapters dealing with hydrocarbon fuels. The topic of hydrocarbon fuels had to be subdivided into several smaller sections that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are: Alkanes, Alkenes and Alkynes, Aromatic Hydrocarbons, Cycloaliphatic Hydrocarbons, Hydrocarbons, Jet Fuels, Kerosenes, and Ramjet Fuels.

## 1 Alkanes

Alkanes, saturated hydrocarbons, have the gross formula

$$C_nH_{2n+2}.$$

For alkanes containing more than three carbon atoms, we differentiate between straight-chain hydrocarbons and branched chain hydrocarbons, e.g., *n*-butane and isobutane:

Most alkanes are obtained by fractionated distillation of petroleum and cracked oil. For the higher alkanes, this does not give pure alkanes, but a mixture of isomers with similar boiling points, often containing cycloaliphatic and aromatic hydrocarbons, along with the alkanes as the main product. The distillation fractions are characterized by their boiling range instead of distinct boiling points such as those used for identification of pure compounds. The fraction from 413 to 523 K (140 to 250 °C) is called “kerosene” and is used as diesel fuel, jet engine fuel, and rocket propellant.

Most hydrocarbon fuels that are used practically are mixtures of alkanes with characteristic boiling ranges. Occasionally, pure alkanes are used as model compounds to obtain reproducible results measuring physical and chemical properties, independent of a mixture composition. This section contains information on pure alkanes, although we realize that (with the exception of methane and propane) they are not used as rocket propellants in the pure state.

The following sections on the physical and chemical properties of kerosenes deal with more than one kerosene at a time, often comparing properties of different distillation cuts that go under different names. Following these sections on kerosenes

in general, there are sections on the physical properties of specific kerosenes, dealing only with one grade of kerosene at a time. These sections are arranged in order of significance and not in alphabetical order. Therefore, in the order of significance for rocket propulsion, RP-1 and RP-2 are discussed first, followed by JP-4 and other kerosenes for air-breathing engines.

## 1.1 Physical Properties of Alkanes

### 1.1.1 Viscosity of Alkanes

The viscosity of alkanes increases with increasing carbon chain length. An extended hard-sphere model was developed that can accurately predict the viscosity of long-chain *n*-alkanes [1]. The method is based on a hard-sphere model that makes use of an universal function relating reduced viscosity to reduced volume. The existing expression for the molar core volume was extrapolated to long-chain *n*-alkanes, whereas the roughness factor was determined from experimental data. A correlation for roughness factor was developed that allowed the extended model to reproduce the available experimental viscosity data on long chain *n*-alkanes up to tetracontane ( $n\text{-C}_{40}\text{H}_{82}$ ) within  $\pm 5\%$ , at a pressure up to 30 MPa. In the dilute gas limit a physically realistic model, based on the Lennard-Jones effective potential, was proposed and used to evaluate the zero-density viscosity of *n*-alkanes to within  $\pm 2.4\%$ .

Another model was developed to predict the viscosity of liquid, *n*-alkane mixtures [2]. It represented a mixture by a single pseudo-component characterized by an appropriate molecular weight and calculated the viscosity by means of a modified, extended hard-sphere model that made use of a universal function relating reduced viscosity to reduced volume. For mixtures that contain *n*-alkanes with a similar number of carbon atoms, the molecular weight of the pseudo-component was simply given by the molecular weight of the mixture. For more asymmetric mixtures, the choice of the molecular weight was a function of the difference in the number of carbon atoms, between the longest and the shortest chain. The developed model, named 1-component Extended Hard-Sphere, predicted the viscosity of binary and multi-component *n*-alkane mixtures with uncertainty of 5%, even when the mixtures contained very long *n*-alkanes.

*n*-Hexadecane is a constituent of RP-1 and RP-2. A correlation for the viscosity of *n*-hexadecane was based upon a set of experimental data that had been critically assessed for internal consistency and for agreement with theory [3]. It is applicable in the temperature range from the triple point to 673 K at pressures up to 425 MPa and along the saturation line.

### 1.1.2 Thermal Conductivity of Alkanes

When correlating the thermal conductivity of methane and ethane at low pressure as well as doing general correlations of the experimental data, a thermal conductivity

anomaly was noted along 295, 318, 350, and 398 K isotherms for ethane [4]. Measurements were made for ethane within a temperature range 295 to 600 K at pressures up to 70 MPa and for methane within the range 100 to 400 K at pressures from 2 to 70 MPa. A simple model was derived to estimate the anomalous conductivity. Some evidence of critical anomaly was also seen along the 200 and 240-K isotherms in the case of methane.

The thermal conductivities of five liquid *n*-alkanes: hexane, heptane, octane, decane, and dodecane were measured within the temperature range 283 to 373 K at pressures up to 250 MPa or the freezing pressures using a transient hot-wire apparatus [5]. The thermal conductivity of each alkane decreased almost linearly with rising temperature at a constant pressure and increased with increasing pressure at a constant temperature. Both the temperature coefficient of the thermal conductivity  $(\partial\lambda/\partial T)_p$  and the pressure coefficient  $(\partial\lambda/\partial P)_T$  decreased with an increasing carbon number of alkanes. The experimental results correlated with temperature and pressure by an expression similar to the Tait equation. It was found that both the dense hard-sphere model and the modified significant structure theory provided good representations of the experimental results.

The thermal conductivity of liquids may be difficult to predict with reasonable accuracy owing to the lack of accurate experimental data and reliable prediction schemes. Data of high accuracy, and covering wide density ranges, obtained using the transient hot-wire technique, can be used to revise an existing correlation scheme and to develop a universal predictive technique for the thermal conductivity of liquid normal alkanes [6]. The correlation scheme was constructed on a theoretically based treatment of the van der Waals model of a liquid, which permits the prediction of the density dependence and the thermal conductivity of liquid *n*-alkanes, methane to tridecane, for temperatures between 110 and 370 K and pressures up to 0.6 MPa, i.e., for  $0.3 \leq T/T_c \leq 0.7$  and  $2.4 \leq P/P_c \leq 3.7$ , given a known value of the thermal conductivity of the fluid at the desired temperature. It was possible to predict the thermal conductivity of pentane to tetradecane to within  $\pm 2\%$ , without the necessity of experimental measurements.

A study of the applicability of an extension of the van der Waals model to predicting the thermal conductivity of binary mixtures of pure liquid alkanes was based upon accurate data for the binary mixtures methane + ethane and *n*-heptane + 2,2,4-trimethylpentane [7]. Reduced thermal conductivity for the mixtures was defined such that its density dependence was identical to that of the pure components. A scheme was developed that enabled the prediction of the thermal conductivity of the mixtures at any temperature  $T \leq 0.7T_c$ , at any pressure, solely from data for the pure components, i.e., without resorting to any experimentally adjusted parameters for the mixtures. Such a scheme was able to reproduce the available thermal conductivity data for the above-mentioned mixed systems with an error of the order of  $\pm 2\%$ , which was commensurate with the combined uncertainty of the experimental results for the pure components and for the mixtures.

Thermal conductivity data for specific hydrocarbons are listed in the subsequent sections. Thermal conductivity data for propane, butane, isobutane, and butylene were summarized and expressed in mathematical form [8].

### 1.1.3 Critical-Point Properties of Alkanes

The critical-point properties of *n*-alkanes are listed in Table 1. Critical temperature and critical density increase with increasing chain length and critical pressure decreases with increasing chain length of the molecules.

**Table 1:** Critical-point properties of *n*-alkanes.

|                    | $M$<br>g/mol | $T_c$<br>K      | $P_c$<br>MPa  | $\rho_c$<br>g/cm <sup>3</sup> | $V_c$<br>cm <sup>3</sup> /mol | $Z_c^a$ |
|--------------------|--------------|-----------------|---------------|-------------------------------|-------------------------------|---------|
| Methane            | 16.043       | 190.564 ± 0.015 | 4.599 ± 0.003 | 0.1627 ± 0.0005               | 98.60                         | 0.286   |
| Ethane             | 30.070       | 305.32 ± 0.04   | 4.872 ± 0.01  | 0.2066 ± 0.003                | 145.5                         | 0.279   |
| Propane            | 44.097       | 369.83 ± 0.1    | 4.248 ± 0.01  | 0.220 ± 0.003                 | 200                           | 0.277   |
| <i>n</i> -Butane   | 58.123       | 425.12 ± 0.1    | 3.796 ± 0.01  | 0.228 ± 0.003                 | 255                           | 0.274   |
| <i>n</i> -Pentane  | 72.150       | 469.7 ± 0.2     | 3.370 ± 0.02  | 0.232 ± 0.003                 | 311                           | 0.268   |
| <i>n</i> -Hexane   | 86.177       | 507.6 ± 0.2     | 3.025 ± 0.02  | 0.234 ± 0.003                 | 368                           | 0.264   |
| <i>n</i> -Heptane  | 100.204      | 540.2 ± 0.3     | 2.74 ± 0.03   | 0.234 ± 0.003                 | 428                           | 0.261   |
| <i>n</i> -Octane   | 114.231      | 568.7 ± 0.3     | 2.49 ± 0.03   | 0.232 ± 0.003                 | 492                           | 0.259   |
| <i>n</i> -Nonane   | 128.258      | 594.6 ± 0.6     | 2.29 ± 0.05   | 0.231 ± 0.005                 | 555                           | 0.257   |
| <i>n</i> -Decane   | 142.285      | 617.7 ± 0.6     | 2.11 ± 0.05   | 0.228 ± 0.005                 | 624                           | 0.256   |
| <i>n</i> -Undecane | 156.312      | 639 ± 1         | 1.98 ± 0.1    | 0.227 ± 0.01                  | 689                           | 0.257   |
| <i>n</i> -Dodecane | 170.338      | 658 ± 1         | 1.82 ± 0.1    | 0.226 ± 0.01                  | 754                           | 0.251   |

<sup>a</sup>  $Z_c = p_c V_c / RT_c$ , where  $R = 8.31451 \text{ Pa m}^3 \text{ mol}^{-1} \text{ K}^{-1}$

Data source: [9]

### 1.1.4 Thermodynamic Properties of Alkanes

The fundamental method for calculating the enthalpies of formation of alkanes is to determine the heats of combustion experimentally in a calorimeter. The enthalpy of formation can be calculated from the heat of combustion assuming complete combustion to carbon dioxide and water. For simple alkane molecules, where experimental data were not available, it was common practice to assume additivity of bond energies and apply certain corrections for branched structures. The most simple calculational approach was to look up bond energies in a table, assume additivity, and this gave qualitatively encouraging results. It was quickly found, however, that “structural features” also had to be included in the calculation if the result was to be more than qualitative. This procedure is taught in university chemistry classes and works reasonably well for many types of compounds, alkanes, and alkane derivatives [10]. The basic method assumes the additivities of the bond energies of various structural features in molecules. The problem here is that although there are large numbers of molecules for

which these structural features do indeed have additive energies, there are also substantial numbers of molecules, in particular those with strained rings of interest as jet engine and rocket fuels, where they do not. Only after molecular mechanics computational methods became available was it possible to calculate and predict strain energies of molecules in a general way. The strain energies for a small set of hydrocarbons ranging in size from 3 to 6 carbon atoms has been calculated using homodesmotic reactions and *ab initio* methods [11]. The strain energy of two larger strained hydrocarbons, quadricyclane and cubane, were calculated and compared with the available experimental data. Unfortunately, this gives only the enthalpy of formation in the gaseous state, but most of our rocket fuels are used as liquids. The enthalpy of vaporization has to be obtained from other sources in order to calculate the enthalpy of formation of alkanes in the liquid state.

A comparison of experimental and computational enthalpies of formation of 50 alkanes showed reasonably good agreement between measured and predicted enthalpies of formation [12].

## 1.2 Chemical Properties of Alkanes

### 1.2.1 Thermal Decomposition of Alkanes

A list of several hundred free-radical reactions that occur during the low temperature (700–850 K) pyrolysis of small *n*-alkane molecules has been assembled and a set of reliable, self-consistent Arrhenius rate parameters has been assigned on the basis of experiment, theory, thermochemical estimates and structural analogy [13]. Rate parameters have been recommended for the following types of reactions, with the number of each type in parentheses: initiation (32), recombination (135), disproportionation (108), H-transfer (112), decomposition (41), addition (58), and isomerization (11), giving a total of 505 reactions. This compilation was intended for use in assembling reaction matrices in computational modeling studies of the thermal reactions of hydrocarbon molecules.

In a study of the vapor-phase thermolysis of several straight-chain alkanes and their mixtures, including C<sub>9</sub>, C<sub>12</sub>, C<sub>13</sub>, C<sub>16</sub>, and C<sub>22</sub>, in a flowing tube reactor at atmospheric pressure and temperatures from 623 to 893 K, the thermolysis of unbranched alkanes yielded a series of 1-alkenes as major products [14]. The 1-alkene selectivity strongly depended upon pressure: the lower the pressure, the higher the selectivity. Straight-chain alkane thermolysis, under any pressure, followed a free-radical mechanism that produced alkenes with double bonds in the  $\alpha$ -position via  $\beta$ -scission of bonds. Low pressure favored radical decomposition over hydrogen abstraction.

The thermal decomposition of C<sub>10</sub>–C<sub>14</sub> *n*-alkanes was studied under near-critical and supercritical conditions [15, 16]. The primary products were C<sub>1</sub>–C<sub>*m*–2</sub> *n*-alkanes and C<sub>2</sub>–C<sub>*m*–1</sub> 1-alkenes, and the secondary products were *cis*- and *trans*-2-alkenes, *n*-C<sub>*m*–1</sub>, *n*-C<sub>*m*+1</sub>, and C<sub>*m*+2</sub>–C<sub>2*m*–2</sub> normal and branched alkanes, where *m* is the num-

ber of carbon atoms in the reactant. The relative yields of the primary and secondary products were dependent on the reaction conditions. Product distributions exhibited large pressure dependence in the near-critical region. The observed product distributions and changes in product composition with reaction conditions were explained by a modified free radical mechanism.

A specific laboratory test bench has been developed that allowed the simulation of a cooling channel as part of a hypersonic scramjet combustion chamber [17]. In order to understand the cracking mechanisms and the behavior of a fuel in a supercritical environment, the thermal cracking of a model fuel (a mixture of linear hydrocarbons:  $n\text{-C}_{10}\text{H}_{22}$ ,  $n\text{-C}_{11}\text{H}_{24}$ ,  $n\text{-C}_{12}\text{H}_{26}$ ,  $n\text{-C}_{13}\text{H}_{28}$ ) was carried out at a high temperature between 873 and 1173 K (600 and 900 °C) and under a pressure of 30 bar. For the lowest temperature (600 °C), and thus at low parent hydrocarbon conversion, the entire range of  $n$ -alkanes with 1 to 9 carbon atoms and all the 1-alkenes with 2 to 10 carbon atoms were obtained. With an increase in temperature, secondary products began to appear. They were isomerized olefins and cyclic hydrocarbons.

In cooling systems where fuels undergo thermal catalytic cracking through endothermic reactions, the fuel is under high pressure and at a high temperature, corresponding to supercritical conditions. A comparison of thermal and catalytic cracking of hydrocarbons under these conditions was made [18]. To catalyze the hydrocarbon cracking reactions, two zeolites, Y and ZSM-5 zeolites, were selected and a parametric study of the thermal and catalytic cracking reactions of a model fuel ( $n$ -dodecane) under supercritical conditions was conducted. The tests were carried out in a stirred batch reactor heated to 698 K (425 °C) and under pressures up to 150 bar. After cooling down, the cracking products were characterized by several analytical techniques in order to determine the influence of the operating conditions on the cracking reaction mechanisms. The efficiency of catalytic cracking with the zeolites Y and ZSM-5 was compared with thermal cracking without catalysts. An increase in operating temperature raised the catalyst degradation rates and the number of cracking products.

Chemical kinetic models of multi-component hydrocarbon fuels decomposition can be used to predict the heat sink capacity, but require knowledge of the chemical kinetic behavior of these compounds during cracking. The heat sink capacity depends on the ratio of saturated  $n$ -hydrocarbons to olefins produced during thermolysis. A chemical kinetic model was developed for thermal and catalytic cracking of  $\text{C}_1$  to  $\text{C}_{16}$   $n$ -paraffins [19]. Predictions for decomposition of  $n$ -octane matched experimental data of  $n$ -octane decomposition over an H-ZSM-5 zeolite catalyst.

### 1.2.2 Radiolysis of Alkanes

Alkanes stored in orbital propellant depots or on board nuclear-propelled space vehicles may be subjected to cosmic radiation or unshielded radiation from the nuclear reactor. Hydrocarbons might even be used as radiation shields to protect more sensitive parts of the spacecraft (the crew cabin) from nuclear radiation. Methane and

lower alkanes present in the atmosphere of gaseous giant planets (e.g., Saturn) and their moons (e.g., Titan) are constantly subjected to cosmic radiation and photolysis, which will eventually convert them to less volatile hydrocarbons of higher molecular mass and the hydrogen will escape the atmosphere.

Methane is a potential fuel produced on the surface of Mars by conversion of indigenous carbon dioxide, a prime example of *In-situ* Resource Utilization (ISRU). If methane has to be stored on the surface of Mars for several years before it can be used, intense radiation may cause some of it to be converted to polymeric resins that might clog the orifices [20, 21]. Liquid methane at 112K has been irradiated by  $^{60}\text{Co}$  gamma rays in the pure state and with small amounts of added ethylene or propylene [22]. The effects of these olefins on products up to  $\text{C}_6$  was interpreted by a simple hydrogen atom-scavenging mechanism. The irradiations were carried to about 0.12% methane decomposition. The loss of methane per unit dose was given as  $G(-\text{CQ}) = 6$  molecules/100 eV. This is approximately 0.01% decomposition per megarad. The major products were hydrogen and ethane, which together accounted for about 95% of the products observed.

Methane, ethane, propane, or ethylene were irradiated to study radiation effects on stored liquid propellants on spacecraft with auxiliary RTG or nuclear power sources [23, 24]. There was fog formation in the gas phase above the liquid and polymer formation in irradiated ethylene.

### 1.2.3 Combustion of Alkanes

The combustion of alkanes as a source of heat is a fundamental process and has been investigated since the early days of chemistry. The chapter at hand contains only a cursory review of burning properties (flammable range, autoignition temperatures in air and in oxygen) of alkanes and specific hydrocarbon mixtures, but the velocity of burning and combustion in rocket engines will be dealt with in later volumes on non-hypergolic rocket propellant combinations. That chapter will deal with combustion of hydrocarbons with liquid oxygen at very high pressures, and not with combustion experiments that can be conducted at ambient pressure in an indoor laboratory. This division of academic papers and engineering designs, both dealing with combustion of hydrocarbons, but from different angles, is similar to that used in *Encyclopedia of Liquid Fuels*, chapter “Hydrogen.”

Combustion is a chemical reaction and therefore combustion mechanisms and burning velocities could be discussed here under chemical properties. However, the burning velocities (flame speeds) of air/alkane and oxygen/alkane flames will be discussed in later volumes on non-hypergolic combinations. The current chapter contains only the safety properties and limits of alkane combustion.

### 1.3 Safety Properties of Alkanes

#### 1.3.1 Flammability Limits of Alkanes

Table 2 gives a summary of flammability limits of alkanes for upward propagation. Additional flammability data are contained in subsequent sections on individual alkanes (See Section 2ff.)

**Table 2:** Flammability limits of alkanes.

| Compound           | Flammability limit, Vol.-% |             |
|--------------------|----------------------------|-------------|
|                    | Lower limit                | Upper limit |
| Methane            | 5.0                        | 15.0        |
| Ethane             | 3.0                        | 12.4        |
| Propane            | 2.1                        | 9.5         |
| <i>n</i> -Butane   | 1.8                        | 8.4         |
| Isobutane          | 1.8                        | 8.4         |
| <i>n</i> -Pentane  | 1.4                        | 7.8         |
| <i>n</i> -Hexane   | 1.2                        | 7.4         |
| <i>n</i> -Heptane  | 1.05                       | 6.7         |
| <i>n</i> -Octane   | 0.95                       | —           |
| <i>n</i> -Decane   | 0.75                       | 5.6         |
| <i>n</i> -Dodecane | 0.6                        | —           |

Data source: [25]

A systematic study of literature data was made to derive mathematical equations that describe the interrelationships of flammability and other properties of *n*-alkanes [26]. The properties that have been correlated are: lower and upper flammability limits, flash point, vapor pressure (at the flash point), flammability index, boiling point, stoichiometric concentration, heat of combustion, molecular weight, and carbon number. Good agreement was found between average literature data and values calculated by the derived equations. From a given flammability property, by use of the derived equations, it is possible to predict the other properties, as well as the relative magnitudes of changes in these properties as a result of a change in ambient starting conditions.

It was demonstrated by a simplified treatment that vapor pressures of individual constituents play a more important role than concentration on the overall flammability properties of hydrocarbon mixtures [27, 28]. This treatment was based on the application of Raoult's and Dalton's laws governing vapor pressure and composition above a solution of two or more liquid hydrocarbons to Le Chatelier's rule governing the flammability of vapor mixtures. The most important conclusion demonstrated by the derived equations was that a very small amount of highly volatile contaminant in a relatively non-flammable fuel may make it flammable. The amounts needed to bring

about this effect can be predicted from the equations and the properties of the components. Although precise relationships have been derived only for relatively simple solutions of pure hydrocarbons, the concepts they imply are applicable to more complex mixtures such as jet and rocket fuels. The flammability properties included in this study were lower and upper flammability limits, flash points, and flammability indices of liquid solutions. Interrelations of the flammability properties of *n*-alkanes in air have been extended to both vapor and liquid fuel mixtures [29].

### 1.3.2 Autoignition Temperature of Alkanes

The autoignition temperature of flammable liquids is determined in accordance with American Society for Testing and Materials (ASTM) D 286-30 and a revised version of the apparatus used by the US Bureau of Mines [25, 30]. The autoignition temperature of alkanes decreases with increasing chain length of *n*-alkanes (Figure 1; Table 3).

**Figure 1:** Autoignition temperature of alkane hydrocarbons. (Reproduced and modified from [25].)

Ignition temperatures of *n*-hexane, *n*-octane, *n*-decane, and JP-6 jet fuel were determined in air using heated Pyrex cylinders and Nichrome wires, rods, or tubes [31]. Ignition temperatures varied little by air : fuel ratio, but increased as the size of the heat source was decreased. In addition, the hot gas ignition temperatures of the combustible vapor-air mixtures were determined with jets of hot air. These ignition tem-

**Table 3:** Autoignition temperature of alkanes.

| Compound          | Autoignition temperature |     |
|-------------------|--------------------------|-----|
|                   | K                        | °C  |
| Methane           | 813                      | 540 |
| Ethane            | 788                      | 515 |
| Propane           | 723                      | 450 |

Data source: [25,30]

peratures also varied little by air : fuel ratio and increased as the diameter of the heat sources was decreased.

### 1.3.3 Detonation of Air/Alkane Mixtures

Explosions and detonations of air/hydrocarbon mixtures have been the cause of numerous accidents [32].

#### 1.3.3.1 Critical Tube Diameter for Propagation of Air/Alkane Detonations

The critical diameter of tubes and orifices for propagation of air/alkane detonations has to be known for the design of flashback arrestors and micro propulsion devices. It is also useful for the design of pulsed detonation engines and rotating detonation engines.

Large-scale tests with mixtures of some common hydrocarbons ( $C_2H_2$  and  $C_2H_4$ ) and air at atmospheric pressure initially confirmed the validity of the  $d_c = 13\lambda$  correlation [33].

During experiments to obtain the critical tube diameter  $d_c$ , for air/ethylene mixtures by investigating the diffraction of detonations from tubes into large plastic bags simulating an unconfined fuel-air cloud, the critical air/ethylene compositions for successful re-establishment of detonation upon emerging from tubes 0.31, 0.45, 0.89, and 1.36 m in diameter were determined by monitoring the diffracted detonation wave in the bag [34].

Results of large-scale experiments on the transmission of air/hydrogen and air/ethylene detonations from a two-dimensional channel into a large open volume confirmed the observations by others that indicated that successful transmission of a detonation emerging from a rectangular orifice with a large aspect ratio  $L/W > 5$ ,

requires the minimum width of the channel to be only about three detonation cell diameters, i.e.,  $W_r \sim 3\lambda$  [35, 36]. The results of direct measurements from different sources are compared in Figure 2 with the estimated values from the  $d_c = 13\lambda$  correlation shown as solid lines for a range of equivalence ratios. From a practical point of view, the empirical law allows reliable estimates of critical tube diameters using cell size data obtained in 1/13-scale experiments. The correlation is particularly valuable for less sensitive air/fuel mixtures, which would require rather large-scale experiments.

**Figure 2:** Variation of critical tube diameter with equivalence ratio in air/ $H_2$  and air/hydrocarbon ( $C_2H_2$ ,  $C_2H_4$ ,  $C_2H_6$ ,  $C_3H_8$ , and  $C_4H_{10}$ ) mixtures at NTP. (Reproduced and modified from [36].)

### 1.3.3.2 Minimum Energy for Initiation of Air/Alkane Detonations

The minimum energy for initiation of air/alkane detonations is illustrated in Figure 3.

**Figure 3:** Variation of critical energy for direct initiation of spherical detonation with fuel percentage in alkane ( $C_2H_6$ ,  $C_3H_8$ , and  $C_4H_{10}$ )-air mixtures at NTP. (Reproduced and modified from [36].)

## 2 Methane

Methane,  $CH_4$ , CAS RN [74-82-8], is in the process of replacing long-established kerosenes as the hydrocarbon fuel in launch vehicles with LOX as the oxidizer. The main commercial candidate for this transition is the Vulcan launch vehicle by United Launch Alliance, propelled by BE-4 engines from Blue Origin, but newcomers such as Starship and Starhopper from Space-X and New Glenn from Blue Origin are also based on using liquid methane as the fuel.

### 2.1 Preparation, Production, and Availability of Methane

Methane is available from natural gas that is either produced from gas wells or escapes from liquid petroleum as soon as it is brought to the surface and the downhole pressure is relieved. Often the methane from remote oil field wells has to be flared off because there is no industrial use for it at those remote locations. Other than in pipelines, methane (natural gas) can be transported as a cryogenic liquid, Liquefied Natural Gas (LNG). LNG has been tested and has flown as a rocket propellant, containing a few other light hydrocarbons in addition to methane.

### 2.1.1 Liquefaction of Methane

The theoretical ideal work required for the liquefaction of methane starting at 300 K and 101.3 kPa is 1091 kJ/kg (469 BTU/lb). The optimized theoretical energy requirement of a Linde-Hampson liquefaction cycle is 3957 kJ/kg (1701 BTU/lb).

### 2.1.2 Physical Properties of Methane

Of all the hydrocarbons in this chapter of the rocket propellants book, methane is the single chemical (as opposed to fuel blends such as RP-1) that has the most literature references to digest and include in this summary. In order to keep the volume of this chapter within manageable limits, not all the data available on the physical properties of methane could be included in full. In most cases, a reference to the literature sources with additional information may suffice [37].

The mini-REFPROP computer program, which can be downloaded free from the web [38], contains methane as an example. It has the capability to create physical and thermochemical property tables and graphs for a wide range of temperatures at the click of a button. Several of the graphs in this section were created using the REFPROP demo version.

Because of the industrial importance of methane, it has become necessary to examine the newly available thermophysical property data and to re-evaluate the older data to produce more useful and accurate correlations. An empirical equation of state for methane based on extensive multi-property analysis, as well as correlations for the liquid/vapor phase boundary and for the viscosity and thermal conductivity of methane, was derived [39]. Tables of coefficients for these correlating equations and graphical representations of the functions for easy accessibility of estimated values of certain properties were included. The correlations were based on a critical evaluation of available experimental data and have been developed to represent these data over a broad range of the state variables. Estimates for the accuracy of the equations and comparisons with measured properties were given, including new and more accurate data, and improvements in the correlation functions, which allow increased accuracy of the correlations, especially in the extended critical region. The resulting equation of state is accurate from about 91 to 600 K for pressures <100 MPa and was developed by considering PVT, second virial coefficient, heat capacity, and sound speed data. For the viscosity of fluid methane, a low-density contribution based on theory was combined with an empirical representation of the excess contribution. The approximate validity range of the resulting correlation was 91 to 400 K for pressures <55 MPa.

### 2.1.3 Freezing Point of Methane

Freezing point measurements reported by various sources are summarized in Table 4. Triple-point data in Table 5 are a compilation from multiple sources, including some of those listed in Table 4.

**Table 4:** Freezing point of methane.

| $P_t$       | 11.696 ± 0.002 kPa                  | 11.696 ± 0.002 kPa |
| $\rho_{tL}$ | 28.145 ± 0.005 mol dm <sup>−3</sup> | —                  |
| $\rho_{tV}$ | 15.66 ± 0.05 mol m <sup>−3</sup>    | —                  |

The melting temperature of frozen methane is dependent on the pressure. Thirteen melting temperatures at pressures up to 21.28 MPa (210 atm) were represented by the Simon equation with a root mean square deviation of 5 kPa (0.05 atm) (0.08%) [44]. This representation is highly sensitive to the triple-point temperature, yielding 90.680 K (ITS-1968). See also Pavese et al. and Inaba and Mitsui [46, 49].

Solid methane exists in several modifications, of which nine are known at this time.

### 2.1.4 Boiling Point of Methane

Boiling point measurements reported by various sources are summarized in Table 6.

**Table 6:** Boiling point of methane.

| SI units           | Other units |            | References |
|--------------------|-------------|------------|------------|
| 111 ± 2 K          | −162 °C     | −260 °F    | [45]       |

| 111.668 ± 0.0025 K | −161.482 °C | −258.67 °F | [51]       |

### 2.1.5 Vapor Pressure of Methane

Three different equations were proposed for calculating the vapor pressure of methane in the range 112.45 to 190.25 K, and two of those are shown here [52]. The first one is essentially the one derived from the Clapeyron-Clausius equation.

$$\log p = A \log T + \frac{B}{T} + C$$

where  $p$  is the vapor pressure in atm and  $T$  is the temperature in kelvin. The constants are  $A = 2.00224$ ,  $B = -394.275$ ,  $C = 0.761227$ . The second equation contains significantly more parameters and promised to give better accuracy data:

$$\log p = \frac{A}{T} + B + CT + DT^2 + ET^3 + FT^4 + GT^5$$

where  $p$  is the vapor pressure in atm and  $T$  is the temperature in kelvin. The constants are  $A = 22028.8$ ,  $B = -902.926$ ,  $C = 15.1525$ ,  $D = -0.134167$ ,  $E = 0.664133 \times 10^{-3}$ ,  $F = -0.174306 \times 10^{-5}$ ,  $G = 0.189568 \times 10^{-8}$ .

The vapor pressure of methane is illustrated in Figure 4.

**Figure 4:** Vapor pressure of methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp)

The vapor pressure of liquid methane can be calculated from the Antoine equation

$$\log P = A - [B/(T + C)]$$

where  $P$  is the vapor pressure in bar,  $T$  is the temperature in kelvin, and  $A$ ,  $B$ , and  $C$  are the constants listed in Table 7 for four different temperature ranges.

**Table 7:** Coefficients for the Antoine equation for vapor pressure of methane for four different temperature ranges.

| Temperature range, K | A       | B       | C       | References |
|----------------------|---------|---------|---------|------------|
| 90.99–189.99         | 3.98950 | 443.028 | –0.49   | [44]       |
| 96.89–110.19         | 2.00253 | 125.819 | –48.823 | [53]       |
| 93.04–107.84         | 3.80235 | 403.106 | –5.479  | [54]       |
| 110.00–190.50        | 4.22061 | 516.689 | 11.223  | [50]       |

Note: Coefficients calculated by National Institute of Standards and Technology from the author's data.

The vapor pressures, heats of vaporization, and heat capacities of methane from boiling point to the critical temperature have been measured [50]. The vapor pressure data in the range 110–190 K have been represented in the form

$$\log P = 3.984667 - (444.6667/T) - \delta T$$

where  $P$  is the vapor pressure in atm,  $T$  is the temperature in kelvin, and where  $\delta T$  is in essence a deviation function. The constants of this equation were arbitrarily chosen so as to minimize the magnitude of  $\delta T$ . The function  $\delta T$  was then tabulated at equal intervals of temperature and the fourth difference smoothed. The normal boiling point of methane from this equation is 111.420 K. Critical constants have been calculated from the vapor pressure data. It was shown that the measured heats of vaporization

Data source: [48]

were in good agreement with those calculated from the above vapor pressure equation and the known liquid and gaseous densities.

Various sources of additional literature data on the vapor pressure of methane are listed in Table 8 in chronological order. The determination of vapor pressure was sometimes only peripheral to other measurements of physical properties.

One hundred and five vapor pressure data points from the triple point to the critical point were represented by a non-analytical equation with a root mean square relative deviation of 0.01% [44]. The derived triple-point pressure was 0.1159 atm. At the assigned critical-point temperature of 190.53 K the pressure was 45.356 atm. Deviations of some of the data from those of other sources exceeded 1% only at  $T < 140$  K.

### 2.1.6 Density of Methane

Based on the results of measurements of the density behavior of liquid methane at high pressures, an equation of state and different thermodynamic properties of methane were calculated in two regions [68]. Fourteen isotherms were determined between 114 and 190 K. The maximum pressure was 31 MPa (4500 psia).

Figure 5 gives the calculated coexisting densities of vapor and liquid methane along the ordinate. The abscissa gives the saturation temperature,  $T_s(\rho)$  [69].

**Figure 5:** Coexisting vapor and liquid densities of methane down to the triple point. (Reproduced and modified from [70].)

The PVT data for liquid methane were measured at densities from 1.8 times critical density up to the density of the freezing liquid, at temperatures from 91 to 245 K and pressures up to 350 bar [71]. A non-analytic equation of state was adjusted to these and

other PVT data from ideal gas states to freezing liquid, at temperatures from the triple point to 400 K; these data cover most of the domain at  $T_t < T < 400$  K, and  $P \leq 350$  bar. The table containing the raw experimental data with temperature increments of 2 K extends over four pages. The isochoric equation of state for methane had the form

$$(Z - 1) \times \frac{\tau}{\rho} = A + B \cdot \Phi(T) + \frac{C}{\tau} + D\Psi(\rho, T).$$

where  $Z = PV/RT$  is the compressibility factor,  $\tau$  is the absolute reduced temperature reduced at the critical point  $\tau = T/T_c$ ,  $\Phi(T)$  is a function of temperature:

$$\Phi(T) = \tau \left[ 1 - \exp\left(-b - \frac{\beta}{\tau}\right) \right]$$

and  $\Psi(\rho, T)$  is a function of density and temperature:

$$\Psi(\rho, T) = \frac{1 - \omega \ln\left(1 + \frac{1}{\omega}\right)}{\tau}$$

where  $\omega$  is  $(T - \Phi)/(\delta T_c)$ .  $\beta$ ,  $\delta$ , A, B, C, and D are constants. The triple-point density of methane is  $d_t = 28.1472$  mol/L. The measured and calculated methane density data were compared with those reported by Vennix [72] and Douslin et al. [73]. The 1964 measurements by Douslin et al. covered a temperature range of 273 to 623 K (0 to 350 °C) and extended to pressures of 1.62 to 40.5 MPa (16 to 400 atm) and densities of 0.75 to 12.5 mol/L. From these data, constants were derived for the Beattie-Bridgeman and Benedict-Webb-Rubin equations of state.

Saturated liquid and vapor densities of pure methane were measured together with the vapor pressure along the whole coexistence curve (ranges covered: 50 to 350 K, 0.01 to 8 MPa, 1 to 2000 kg/m<sup>3</sup>) [51]. Densities of the homogeneous gas could also be measured. The density measurements compensation method was based on Archimedes' buoyancy principle. Instead of the usual single sinker, two sinkers that had identical mass and surface area but that differed considerably in volume were used. A magnetic suspension coupling transmitted the suspension force without contact from the pressure cell to a microbalance (resolution: 10<sup>-5</sup> g) at ambient atmosphere. The saturated vapor densities were determined in quite a new way. As a first substance, methane (purity 99.9995 mol-%) was investigated from the triple-point temperature (90.685 K) up to 0.02 K below the critical temperature. Critical values were derived from these measurements:  $T_c = 190.551$  K,  $\rho_{n,c} = 10.139$  mol/L,  $p_c = 4.5992$  MPa.

Densities on three isotherms (189, 190, and 193 K) of the homogeneous part of the critical region were measured in the density range from 60 to 260 kg/m<sup>3</sup> ( $\rho_c = 162.660$  kg/m<sup>3</sup>) [74].

A truncated virial equation with only three adjusted parameters has been established for the range 273.15 to 323.15 K at pressures up to 8 MPa, which represented the

density of methane with an uncertainty of less than  $\pm 0.01\%$  [75]. The density under standard conditions (273.15 K, 0.101325 MPa) was calculated from this equation as  $\rho_s = (0.71746 \pm 0.00007) \text{ kg/m}^3$ . See also Kleinrahm et al. and Haendel et al. [76, 77].

In a compilation of thermophysical properties of methane, a tabulation containing 16 literature sources of PVT data of methane was used to derive a very accurate equation of state. In the phase diagram in Figure 6, the critical point is indicated by a black circle. The phase boundaries were derived from ancillary equations. A similar chart is available in the same publication for the isochors.

**Figure 6:** Methane isotherms derived from the SW Equation of State. (Reproduced and modified from [39], with permission of ©1989 AIP Publishing; permission conveyed through Copyright Clearance Center Inc.)

The PVT isotherms of methane and propene have been determined between 1 and 10 kbar at temperatures of 308, 373, and 473 K (35, 100, and 200 °C) [78].

Density measurements on pure methane in the range 273 to 323 K, 0.1 to 12 MPa, and 1 to 1000 kg/m<sup>3</sup> density with a total uncertainty in density less than  $\pm 0.02\%$  used a “Two-Sinker Method,” which is based on Archimedes’ buoyancy principle [79]. Comprehensive ( $P$ ,  $\rho$ ,  $T$ ) measurements on pure methane were taken within the entire working range of the apparatus with respect to temperature and pressure. Truncated virial equations were established for the investigated region of methane and the experimental results were compared with results of previous workers and with current equations of state.

Comprehensive ( $P$ ,  $\rho$ ,  $T$ ) measurements on pure methane (159 values) have been made within the temperature range 240 to 520 K at pressures up to 30 MPa [80]. The

measurements were performed using a single-sinker densimeter that was based on Archimedes' buoyancy principle. The total relative uncertainty of the measurements in the density  $\rho$  was estimated to be  $\leq (1.5 \text{ to } 2) \times 10^{-4} \cdot \rho$  for methane. The measurements were compared with previous results of other experimentalists and with values calculated from current equations of state.

The density of liquid methane along the saturation line under saturation pressure can be simply calculated and graphed using data from the demonstration version of REFPROP (Figure 7).

**Figure 7:** Density of liquid methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

### 2.1.6.1 Equations of State for Methane

The data on the thermodynamic properties of methane that were available up to the middle of 1991 were reviewed and formed the foundation for a new equation of state in the form of a fundamental equation explicit in the Helmholtz free energy [48, 81]. Independent equations were also included for vapor pressure, saturated liquid and vapor densities, the isobaric ideal gas heat capacity and the melting pressure as functions of temperature. Tables for the thermodynamic properties of methane from 90 to 620 K for pressures up to 1000 MPa were presented. For the density, uncertainties were estimated to be  $\pm 0.03\%$  for pressures below 12 MPa and temperatures below 350 K and  $\pm 0.03\%$  to  $\pm 0.15\%$  for higher pressures and temperatures. For the velocity of sound, the uncertainty ranged from  $\pm 0.03\%$  to  $\pm 0.3\%$  depending on temperature and pressure. Heat capacities may be generally calculated within an uncertainty of  $\pm 1\%$ . To verify the accuracy of the new formulation, the calculated property values were compared with selected experimental results and existing equations of state for methane from the lit-

erature. The new equation of state corresponds to the new International Temperature Scale of 1990 (ITS-90) and can be extrapolated up to pressures of 20000 MPa. After a critical evaluation of all the data it was concluded that measurements before 1950 did not meet the present quality requirements. Therefore, the Setzmann and Wagner 1991 review [48] included only all experimental investigations that had been carried out during the period 1950–1990 or older works that were of essential importance for the characterization of the data situation of single properties of methane.

Table 9 is a summary of the equations of state for methane that have been developed since 1970. All of these wide-range equations of state are based mainly on the  $P\rho T$  data (pressure  $P$ , density  $\rho$ , temperature  $T$ ) published by Douslin et al. [73], Cheng [82], Goodwin and Prydz [71], and Sievers and Schultz [83]. All equations of state listed in Table 9 may contain errors of at least  $\pm 0.2\%$  in density in a wide range of temperatures and pressures.

**Table 9:** Summary of the literature on equations of state for methane.

Data source: [48]

The original report contains 40 tables for a wide range of pressures from 0.101 to 100 MPa. Instead of saturated liquid conditions, the thermodynamic properties of liquid methane at two selected pressures are listed in Table 11.

The density of gaseous methane has been measured in the temperature range 253–423 K (–20 to +150 °C) and in the pressure range 130–690 MPa, using a substitution method [96]. The overall uncertainty in the results was 0.03% at the 95% confidence level. The data were presented in the form of a modified Benedict-Webb-Rubin equation of state and were compared with the results of other workers.

It is difficult enough to obtain accurate equations of state for methane in equilibrium with its environment, but it is even more difficult to describe methane in the superheated liquid state. Measurements of densities of liquid methane in stable and metastable phase states were carried out within the temperature range 144 to 185 K [97]. The depth of penetration into the metastable region was 1.5 MPa and 43.6 K. An equation of state for superheated liquid methane was proposed. The density of the liquid at the line of attainable superheats has been determined. The spinodal curve has been approximated. For compositions within this curve, infinitesimally small fluctuations in composition and density will lead to phase separation via spinodal decomposition.

An equation of state was developed for the thermodynamic properties of methane in the vicinity of the critical point [98]. It incorporated the scaled asymptotic critical behavior predicted theoretically and supplemented a global analytic equation of state for methane developed by Setzmann and Wagner. See also Cheng [82].

**Table 11:** Thermodynamic properties of liquid methane at two selected pressures.

### 2.1.6.2 Densified Liquid Methane

Similar to densified oxygen and densified hydrogen, densified liquid methane has been evaluated for a number of space missions.

Methane gas of 99% purity was condensed to liquid methane, and methane slush was subsequently produced using the freeze-thaw method [99] in the following manner:

- (1) The surface of the liquid was pumped to the triple-point pressure, 11.6 kPa (87.7 mm Hg).
- (2) Pumping was continued until a solid layer formed on the top of the liquid.
- (3) The pumping was stopped and soon the solid layer melted at the Dewar flask walls and settled into the liquid.

Stirring at this time helped to break the solid and encouraged settling. The cycle was then repeated. The slush became more dense and the solid particles no longer tended to settle out of the liquid. An apparatus was assembled that allowed solid particles to be photographed in triple-point liquid with a reference grid in the background. Fresh and aged solid particles were photographed. Photos of the particles indicated a definite aging effect between fresh and 4-h-old particles. Particles of two different size ranges appeared during the production process. One group of particles appeared to be within the range  $\geq 2\text{ mm}$ , and when stirred, these particles settled within a short time (15 s) to the bottom of the Dewar. Another much smaller group of particles, with diameters  $\sim 0.2\text{ mm}$  or less were present immediately after forming solids but coalesced with time.

The cryogenic option for an Altair Lunar Lander was envisioned to use liquid oxygen and liquid methane to propel Altair from the lunar surface back to rendezvous with the Orion command module. It was determined that the liquid methane should be densified by subcooling it to 93 K in order to prevent over-pressurization of the propellant tanks during the 210-day stay on the lunar surface. A trade study was conducted to determine the preferred method of producing, loading, and maintaining the subcooled, densified liquid methane onboard Altair from a ground operations perspective [100]. The desired delivery temperature of the methane at 93 K would be only 2.3 K above the methane triple point of 90.7 K. Twenty-six methods of subcooled liquid methane production and delivery along with the associated system architectures were investigated to determine the best solutions to the problem, including slush methane with  $\text{LCH}_4$  at its triple point with 50% solid  $\text{CH}_4$ . The top four cryogenic processing solutions were selected for further evaluation and detailed thermal modeling.

### 2.1.7 Compressibility and Velocity of Sound of Methane

The adiabatic compressibility of liquid methane along the saturation line under saturation pressure is illustrated in Figure 8. The isothermal compressibility of liquid methane along the saturation line under saturation pressure is illustrated in Figure 9. The velocity of sound in liquid methane along the saturation line under saturation pressure is illustrated in Figure 10. Table 12 shows a summary of additional literature on the velocity of sound data in methane.

Sound velocity measurements were carried out in liquid methane between its triple and critical point [57]. Some thermodynamic properties (specific heats, compressibilities, expansion and pressure coefficients) were derived and were in good agreement with the few available and directly measured data.

Sound velocity in liquid methane for pressures up to 200 atm was measured along seven isotherms between the triple point (91 K) and the critical point (191 K) [101]. Adiabatic compressibilities have been calculated by combining these results with density data.

**Figure 8:** Adiabatic compressibility of methane. (Image generated by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

**Figure 9:** Isothermal compressibility of methane. (Image generated by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

A piezometric method was used to measure the density and isothermal compressibility of liquid methane at  $T = 90\text{--}130\text{ K}$  and  $P$  up to 500 atm [105]. The compressibilities were calculated as a function of  $P$  and  $T$ . The bulk modulus showed a linear dependence on  $P$ . The slopes of these straight lines did not depend on  $T$ . The bulk strengths of methane depended on  $T$  and obeyed the law of corresponding states.

**Figure 10:** Velocity of sound in liquid methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

**Table 12:** Literature on the velocity of sound in methane.

Data source: [39]

The velocity of sound in saturated and compressed fluid methane was measured on the saturated liquid from 91 to 186 K and on the compressed fluid along selected isotherms from 100 to 300 K at pressures up to about 35 MPa [102]. Data were combined with literature  $P\rho T$  data to obtain the isentropic compressibility and the ratio of the specific heats. Measurements along the higher temperature isotherm were limited to densities greater than about 10 mol/L at 300 K increasing to about 14 mol/L at 210 K owing to the large low pressure sound attenuation in methane.

The velocity of sound and derived values of the constant volume heat capacity in methane were determined as functions of temperature and pressure along the phase

boundaries, at 298 K, and at densities from 0 to 11.6 mol/L for temperatures from 113.5–193.05 K [67]. Velocity dispersion arising from vibrational relaxation, relaxation near the critical point, and relaxation near the triple point were characterized. The results were tested by use of extended thermodynamic scaling representations for the chemical potential  $\mu$ . Within the limits of possible computational errors, the results indicated that along the critical isochore,  $(\partial^2\mu/\partial T^2)_p$  is finite, non-zero, and has a jump discontinuity at the critical temperature that implies that  $\varepsilon = 2$ ,  $(\beta + \alpha) = (1/2)$ , and  $\alpha = (1/7)$ , where  $\alpha$ ,  $\beta$ , and  $\varepsilon$  are scaling exponents.

The principal Hugoniot of liquid methane has been measured between 5 and 43 GPa and a doubly-shocked state has been measured at 91 GPa [106]. The repulsive pair potential for methane was demonstrated to obey the principle of corresponding states.

The absolute determination of the refractive index, when combined with an expansion technique for obtaining the higher-order coefficients of the Lorentz-Lorenz expansion, can lead to precise values of density and compressibility [107]. A grating interferometer was used for the refractive index measurements as a function of pressure. The advantage of a grating interferometer was that it performed reversible counting and generated a DC-compensated signal from the interference fringes. The pressure was measured with an interferometer, previously calibrated with an oil-type precision piston gauge. For the precise determination of the compressibility factor, the absolute measurement of the refractive index was combined with the differential technique to determine the refractivity virial coefficients of the Lorentz-Lorenz expansion. The compressibility factors of methane, nitrogen, and their mixtures have been determined at 323.15 K for pressures up to 335 bar. The optical method for the determination of the compressibility factor not only was precise but also had the ability to produce numerous experimental points in a relatively short time compared with other time-consuming methods.

## 2.1.8 Viscosity of Methane

### 2.1.8.1 Viscosity of Liquid Methane

The dynamic viscosity of methane under saturation pressure conditions is illustrated in Figure 11. Table 13 gives the viscosity for the saturated liquid at saturation pressure. The same data are graphed in Figure 12.

In contrast to propane (Vogel et al. 1998) there is no dramatic rise in the viscosity in the liquid phase at low temperatures and high densities. See also Assael et al. [109].

**Figure 11:** Dynamic viscosity of liquid and gaseous methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

**Table 13:** Density and viscosity of methane-saturated liquid at saturation pressure.

| Temperature<br>K | Density |       | Dynamic viscosity                   |       |
|------------------|---------|-------|-------------------------------------|-------|
|                  | mol/L   | g/mL  | $\mu\text{g cm}^{-1} \text{s}^{-1}$ | cPs   |

### 2.1.8.2 Viscosity of Gaseous Methane

Sources of viscosity data of methane at elevated pressures are summarized in Table 14.

The viscosity of methane gas can be correlated by the equation

$$\mu(\rho, T) = \mu_0(T) + \mu_1(T)\rho + \Delta\mu'(\rho, T)$$

where  $\mu_0$  is the viscosity of the dilute gas and the term  $\mu_1$  is the first density correction for the moderately dense gas, given by the empirical expression

$$\mu_1(T) = A + B \left[ C - \ln \left( \frac{T}{F} \right) \right]^2$$

where  $T$  is the temperature in kelvin,  $A$ ,  $B$ , and  $C$  are constants and  $F = \epsilon/k = 168.0\text{ K}$  where  $\epsilon$  is the energy parameter of the methane pair potential function and  $k$  is the Boltzmann constant. The term  $\Delta\mu'(\rho, T)$  is expressed empirically by a complicated, empirical equation with many parameters [108, 119]. Similar equations have been derived for thermal conductivity. Calculated viscosity data were tabulated for temperatures between 95 and 500 K and pressures between 0.1 and 50 MPa.

The standard reference viscosity of methane gas at 298 K and 101 kPa is  $11.0769\text{ }\mu\text{Pa}\cdot\text{s}$ .

Figure 13 illustrates the viscosity of gaseous methane as a function of density, which is a function of both temperature and pressure, for three isotherms.

**Table 14:** Sources of viscosity data of methane at elevated pressures.

Figure 14: Surface tension of methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

The differential method of capillary rise was used to determine the temperature dependence of the surface tension of liquid Kr, CH<sub>4</sub>, CD<sub>4</sub>, and LOX over the entire range of temperatures at which they exist in the liquid form at ambient pressure [124]. The results were tabulated and shown graphically along with the other experimental data. The results can be described by the van der Waals equation. The deviations from the

law of corresponding states were discussed for a large number of substances and reasons for the deviations were considered.

The surface tension,  $\sigma$ , versus temperature relations of liquefied gases Ar, Kr, CH<sub>4</sub>, CD<sub>4</sub>, O<sub>2</sub>, CF<sub>4</sub>, and H<sub>2</sub>, were determined by the capillary rise method [125]. The experimental results were used to test the validity of known empirical and semi-empirical equations relating surface tension  $\sigma$  to temperature  $T$ . Based on the free volume theory of liquids, a new equation for  $\sigma$  was derived. The surface tension values calculated from this equation agreed with experimental values only at temperatures below the boiling point.

The surface tension of liquid methane as a function of temperature can be expressed by the equation

$$\eta = 33.97 - 0.1891T$$

where  $\eta$  is the surface tension in mN/m and  $T$  is the temperature in kelvin [123].

Surface tension liquid acquisition devices can be used within a propellant tank in space to deliver single-phase liquid to the engine in low gravity. One type of liquid acquisition device is a screened gallery whereby a fine mesh screen acts as a “bubble filter” (bubble trap) and prevents the gas bubbles from passing through until a crucial pressure differential condition across the screen, called the bubble point, is reached. Surface tension propellant management devices (PMD) bubble point data were measured in liquid methane for stainless steel Dutch twill screens with mesh sizes of 325 × 2300 and 200 × 1400 wires per inch [126]. Data were presented for both saturated and sub-cooled liquid methane, and were compared with predicted values.

### 2.1.10 Thermal Conductivity of Methane

The thermal conductivity of methane under saturation pressure conditions is illustrated in Figure 15.

The thermal conductivity of methane was measured in the liquid and dense gaseous states using an absolute transient hot wire apparatus at temperatures between 120 and 400 K and at pressures ranging from 25 to 700 bar, as illustrated in Figures 16 and 17 [127]. Maximum uncertainty in the results due to systematic and random errors in the apparatus and the measurement techniques was less than 1%. Gas-chromatographic analysis of methane samples showed 99.33% methane, 0.56% nitrogen, ethane, and traces of propane. Although several investigators have reported data, very few have covered wide ranges of temperature and pressure. The method used for the present measurements was the solution of the transient true problem for an infinite source of constant heat generation, situated in an unbounded isotropic opaque fluid, initially at local thermodynamic equilibrium. A fine vertical platinum (25  $\mu$ m diameter) wire immersed in the fluid was heated electrically.

**Figure 15:** Thermal conductivity of methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

**Figure 16:** Isobars of thermal conductivity of liquid methane as a function of temperature. (Reprinted and modified from [127], with permission by ©1973 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

**Figure 17:** Isotherms of thermal conductivity of liquid methane as a function of pressure. (Reprinted and modified from [127], with permission by ©1973 Springer Nature; permission conveyed through Copyright Clearance Center Inc.)

The temperature transient of this hot wire for large values of dimensionless time was approximated. The temperature rise at the surface of the wire was measured as a function of time. The thermal conductivity may be obtained after correcting for the effects of the finite heat capacity of the wire, non-constant heat generation parasitic heat losses, and radiation (both surface and fluid). Outside the critical region the thermal conductivity of both liquid and dense gaseous methane increased with density and temperature. An enhancement of  $k$  has been observed as the temperature and density approached their critical values. A pre-freezing anomaly is suspected at low temperatures and higher densities in the vicinity of the triple point. The density correlation of the data seems to confirm the existence of the theoretically predicted logarithmic density dependence of thermal conductivity. Table 16 gives a summary of literature sources for thermal conductivity data for methane, arranged in chronological order.

**Table 16:** Sources of thermal conductivity data for methane at elevated pressures.

Data source (in part): [39]

The thermal conductivity of methane can be correlated by the equation

$$\lambda(\rho, T) = \lambda_0(T) + \lambda_1(T)\rho + \Delta\lambda'(\rho, T)$$

where  $\lambda_0$  is the thermal conductivity of the dilute gas, the term  $\lambda_1$  is the first density correction for the moderately dense gas, given by the empirical expression

$$\lambda_1(T) = A + B \left[ C - \ln \left( \frac{T}{F} \right) \right]^2$$

where A, B, and C are constants and  $F = \epsilon/k = 168.0$  K where  $\epsilon$  is the energy parameter of the methane pair potential function and  $k$  is the Boltzmann constant. The term  $\Delta\lambda'(\rho, T)$  is expressed empirically by a complicated, empirical equation with many parameters [108, 119]. Similar equations have been derived for viscosity. Calculated thermal conductivity data were tabulated for temperatures between 95 and 500 K and pressures between 0.1 and 50 MPa. Table 17 gives the thermal conductivity for the saturated liquid at saturation pressure. The same data are graphed in Figure 18 for an easy overview.

**Figure 18:** Thermal conductivity of liquid methane along the saturation line. (Image created by Schmidt 2020 based on data from [108].)

#### 2.1.10.1 Thermal Conductivity of Methane in the Supercritical State

The thermal conductivity of methane was measured at temperatures from 308 K down to 190.585 K, which is just 21 mK above the critical temperature, and at densities up to 14 mol/L [143]. The data were obtained with a guarded parallel-plate cell with a cryostat that was built especially for measurements in the critical region of methane. The experimental data had greater accuracy than those reported previously in the literature and enabled an examination of the validity of the currently available theoretical description of the asymptotic and non-asymptotic behavior of the thermal conductivity of fluids in the critical region. Equations for the thermal conductivity of methane within a wide range of temperatures and densities were presented.

Similar data were obtained for an equimolar mixture of methane and ethane very close to the critical point and confirmed that the thermal conductivity of a mixture does not diverge at the vapor-liquid critical point but crosses over to a finite limiting behavior at the critical point [144, 145]. An extension of the mode-coupling theory for dynamic critical phenomena in mixtures gave a good quantitative description of the experimental thermal conductivity data.

The conditions of methane flowing through the cooling jacket of a liquid rocket engine are close to its critical point, complicating cooling analysis. An open-source computational fluid dynamics (CFD) method for analysis of methane cooling channels was validated with experimental data, showing an accuracy within 20 K for wall temperature and 10% for pressure drop [146, 147]. It was shown that the turbulence model had only a limited impact on the simulation results and that the wall function approach generated valid results. A cooling channel analysis was performed to compare two thrust chamber materials. A traditional copper alloy was compared with aluminum as a chamber material for a small moderate-pressure oxygen/methane rocket engine. The analyses showed that aluminum is a feasible chamber material only if a thermal barrier coating is applied. A significantly higher cooling channel pressure drop was incurred for an aluminum chamber than for a copper chamber owing to the lower allowable temperature. See also [109].

#### 2.1.10.2 Thermal Diffusivity of Methane

Thermal diffusivity is defined as thermal conductivity divided by density and specific heat capacity at a constant pressure. The thermal diffusivity of methane along the critical isochore at temperatures to within 0.001 K of the critical temperature was measured by Rayleigh light scattering [148]. The results, corrected to zero wave vector, were compared with values from an expression introduced previously. Agreement was within 10%. Some possible reasons for this discrepancy were given.

#### 2.1.11 Heat Transfer Coefficient of Liquid Methane

The knowledge of the heat transfer coefficient of liquid methane is necessary for the design of cooling systems in regeneratively cooled rocket engines. The modeling of liq-

liquid methane coolant flow is a challenging task because of its particular features, such as the high wall temperature gradient, the high Reynolds number, and the three-dimensional geometry of the passages. In the case of methane as a coolant, a further complication is the trans-critical operating condition of the fluid. In this thermodynamic regime large changes in the fluid properties can greatly influence the coolant flow-field and the heat transfer.

High-pressure methane cooling and coking characteristics were evaluated using stainless-steel-heated tubes at methane bulk temperatures and coolant wall temperatures typical of advanced engine operation, except at lower heat fluxes as limited by the tube material [149, 150]. As expected, no coking was observed. However, coking evaluations need to be conducted with a copper-base surface exposed to the methane coolant at higher heat fluxes approaching those of future high chamber pressure engines.

The heat transfer to liquid methane was studied in a liquid methane cooled thrust chamber [151]. An injector with 18 coaxial elements and two types of combustors, which had the same chamber contour except for chamber length and coolant geometry, were employed for the tests. The chamber pressure was 3.5 to 9.2 MPa and the mixture ratio was 2.7 to 5.2. The characteristic velocity  $c^*$  efficiency achieved was 90 to 95%. The maximum heat flux loaded to the nozzle throat region was approximately 80 MW/m<sup>2</sup>.

A series of heat transfer tests with methane was conducted at pressures of 0.5–30 MPa, flow velocities of 2–106 m/s, and heat fluxes up to 66 MW/m<sup>2</sup> in stainless-steel and copper tubes, and the deposit formation rates for kerosene in tubes were measured [152]. Forced convective heat transfer correlations were obtained for liquid methane, propane, and kerosene, up to extreme heat fluxes at which test tubes burnt out. The test results indicated that heat transfer coefficients of methane and propane decreased at high wall temperatures. No coking was detected in methane tests.

In order to compute methane cooling performance and to solve the thermal problem, a one-dimensional FORTRAN code has been developed [153]. With the integration of CHEMKIN II subroutines, starting from propellant temperatures and mixture ratio the code is capable of calculating chemical equilibrium along the entire thrust chamber (combustion chamber and nozzle). In one example of a cooling system design, methane entered the cooling circuit as a liquid state and owing to heat exchange its temperature rose and its density decreased. However, because pressure is greater than critical pressure ( $P_c = 46.5$  bar), no phase change occurs and methane undergoes supercritical transition ( $T_c = 190.4$  K). In order to predict wall temperatures and to solve the thermal problem, properties of liquid and supercritical methane must be provided.

Measurements were carried out to investigate the pool-boiling behaviors of pure methane and three binary mixtures of methane + ethane, methane + propane, and methane + isobutane, as well as a multi-component mixture of methane, ethane, propane, and isobutane at cryogenic temperatures [154, 155]. The measurements

were performed in a descending heat flux procedure ranging from 250 to 30 kW/m<sup>2</sup> at a fixed pressure of 0.13 MPa. Comprehensive measured data were compared with some existing correlations. The deviations between the measured data and the predicted results were within a  $\pm 25\%$  range.

Liquid methane, which is used for regenerative cooling of rocket thrust chambers can flow in channels at supercritical pressures and in the neighborhood of pseudocritical temperature (near-critical fluid), for instance, in liquid-oxygen/liquid-methane rocket engines with chamber pressures greater than about 50 bar [156]. When the fluid is in such a near-critical condition, deterioration in heat transfer can occur if the heat transfer level is higher than a threshold value. Aiming to improve flow prediction capabilities for the design of such systems, numerical calculations of near-critical fluids flowing in uniformly heated straight tubes were conducted. After code validation against experimental data of near-critical-hydrogen flow, numerical simulations of near-critical-methane flow in heated tubes were carried out, each characterized by a different wall heat flux. The near-critical methane flow condition that exhibited the worst heat transfer deterioration was identified.

Heat transfer measurements in flowing liquid and two-phase methane were conducted at the NASA Glenn Research Center Heated Tube Facility using resistively heated tube sections to simulate conditions encountered in regeneratively cooled rocket engines [157]. Several test runs were conducted using three different diameter Inconel 600 tubes, with nominal inner diameters of 0.57, 1.37, and 1.90 mm (0.0225, 0.054, and 0.075 in). The mass flow rate varied from 2.3 to 31.7 g/s (0.005 to 0.07 lb<sub>m</sub>/s). As the focus was on pressure-fed engines for LOX/LCH<sub>4</sub>, the average test section outlet pressures were targeted to be 1.38 or 3.45 MPa (200 or 500 psia). The heat flux was incrementally increased for each test condition while the test section wall temperatures were monitored. A maximum average heat flux of 1013 W/cm<sup>2</sup> (6.2 BTU in<sup>-2</sup>s<sup>-1</sup>) was achieved and, at times, the temperatures of the test sections reached in excess of 1000 K (1800 °R). The primary objective of the tests was to produce heat transfer correlations for methane in the liquid and two-phase regime. For two-phase flow testing, the critical heat flux values were determined where the fluid transitions from nucleate boiling to film boiling. A secondary goal of the testing was to measure system pressure drops in the two-phase regime.

A numerical study of the turbulent convective heat transfer of cryogenic methane used a horizontal minitube under supercritical pressure and data analysis was based on a complete set of conservation equations and accurate evaluations of the thermophysical properties [158]. The numerical investigations focused on a fundamental understanding of the many key parameters, including the inlet pressure, wall heat flux, inlet velocity, inlet temperature, on the supercritical heat transfer phenomena, and the variations of the Nusselt number. Results indicated that bulk property variations at the pseudocritical temperature under a supercritical pressure would cause local heat transfer deterioration. Increasing the inlet methane pressure would result in improved heat transfer at supercritical pressures, particularly under a high wall heat flux, i.e.,

7 MW/m<sup>2</sup>. The conventional empirical expression, i.e., the Gnielinski equation, cannot be used for the heat transfer predictions of cryogenic methane at supercritical pressures. Instead, a modified heat transfer expression that is applicable to supercritical cryogenic methane was successfully established in this study.

A heat transfer test rig was built with the goal of characterizing the heat transfer characteristics of liquid methane as it passes through a heated channel in the regenerative cooling jacket of a rocket engine [159]. The test rig was designed to replicate the conditions in a regenerative cooling channel in a rocket engine. Experiments were first completed using liquid nitrogen in vacuum, resulting in temperature data that showed evidence for boiling in the channel, causing vapor lock.

The LOX/methane engine firing tests were conducted with a thoroughly instrumented engine with many measurement points [160]. Measurements were made to verify the accuracy of prediction models for coolant pressure drop and increase in coolant temperature. A semi-empirical model predicted a pressure drop and temperature increase correctly, but was not able to correctly predict local temperatures around the nozzle throat.

Three-dimensional numerical analyses have been conducted for turbulent supercritical heat transfer of cryogenic methane flowing in a rectangular engine cooling channel with asymmetric heating on the top channel surface, investigating the effects of operational pressure, wall heat flux, and channel geometric ratio on supercritical heat transfer rates [161]. The results indicated that the operational supercritical pressure and wall heat flux would exert significant influences on supercritical heat transfer through their strong effects on physical property variations. Heat-transfer deterioration could occur during supercritical heat transfer, owing to property variation anomalies near the pseudocritical temperature in a near-wall zone. Increasing the operational supercritical pressure would alleviate heat-transfer deterioration. It was found that a shallow cooling channel performed well for supercritical heat transfer but suffered severe pressure loss. The Bishop heat-transfer correlation was tested to be applicable for supercritical heat-transfer predictions of cryogenic methane under certain conditions.

Numerical simulations of trans-critical methane flow-field in an asymmetrically heated rectangular channel with a high aspect ratio and strong wall temperature differences were carried out by a suitable CFD solver and compared with supercritical methane flow-fields [162]. The aspect ratio effect on methane flow was analyzed by comparison of four different rectangular cooling channel geometries with fixed hydraulic diameter and coolant flows with the same mass flow-rate per unit area that influenced fluid-cooling performance and pressure loss.

Often approximated as pure methane, liquefied natural gas (LNG) is a mixture of methane, other heavier hydrocarbons, and nitrogen. If LNG is to be used in a regeneratively cooled liquid rocket engine, knowledge of the thermodynamic and heat-transfer characteristics when it flows into the cooling channels is of primary importance. A parametric study was carried out to understand how the composition

of LNG can influence the flow in the cooling channels, considering different LNG compositions and heat flux levels [163]. The main concern was chemical composition-induced changes in the pressure drop and cooling capabilities, which are the aspects that have to be controlled in a regenerative cooling system.

The characteristics of film cooling in a LOX/LCH<sub>4</sub> subscale rocket engine chamber with multi-injector elements and two kinds of film-cooling slot dimensions were investigated using a calorimeter chamber in experiments and simulations, in which the finite rate chemistry with a reduced O<sub>2</sub>/CH<sub>4</sub> reaction mechanism was taken into account [164, 165]. The computed wall heat flux and pressure distributions were compared with the experimental results, which overall showed good agreement. A large slot dimension was shown to induce mixing with core flow. This mixing caused a low heat-flux distribution near the face plate along with high combustion efficiency.

The heat-transfer characteristics of liquid methane were investigated as part of the design of a methane-condensing mobile unit to supply the laboratory with liquid methane, including heat-transfer coefficient behavior, non-dimensional correlations, different flow conditions, varied inlet conditions, and varied heat flux for a subscale test article applicable to a regenerative cooled rocket engine cooling channel [166]. Test conditions ranged from 1.03 to 2.07 MPa (150 to 300 psi) supply tank pressure, and heat fluxes of 3.9 to 19 MW/m<sup>2</sup> (2.39 to 11.6 BTU in<sup>-2</sup> s<sup>-1</sup>) at turbulent Reynolds numbers (15000 to 360000), including transient and steady-state heat-transfer response.

Measurements of the steady-state heat-transfer characteristics of liquid methane (LCH<sub>4</sub>) under forced convection were made in a 1.8 × 1.8 mm square channel representative of those found in regeneratively cooled rocket engines [167–169]. A High Heat Flux Test Facility was designed to handle cryogenic fluids while maintaining high heat fluxes between 3.3 and 20.0 MW/m<sup>2</sup>. The average Nusselt number Nu<sub>D</sub> reached as high as 336 and the average Reynolds numbers Re<sub>D</sub> were between 1.9 × 10<sup>4</sup> and 1.6 × 10<sup>5</sup>. A Nusselt number correlation (Nu<sub>0</sub>) used by the NASA Rocketdyne III computer program demonstrated an overprediction inaccuracy primarily with Reynolds numbers within the range 6.0 × 10<sup>4</sup> to 1 × 10<sup>5</sup>, whereas the majority of the overpredictions were between 1 × 10<sup>5</sup> and 1.1 × 10<sup>5</sup>.

The expected wall and coolant behavior of a test article simulating rocket engine cooling channels was analyzed by a three-dimensional conjugate heat transfer model [170]. Different coolant pressure and surface roughness levels were considered in order to understand their influence on the heat-transfer capability of the cooling system. Results showed that heat-transfer deterioration may occur in principle when methane is operated under near-critical conditions. The resultant wall temperature profile peak decreased with increasing coolant pressure and increasing surface roughness.

The steady-state heat transfer characteristics under internal forced convection of liquid methane were experimentally investigated using a rectangular channel with a cross section of 1.8 × 4.1 mm and square channels with a cross section of 3.2 × 3.2 mm [171]. Three square channels had surface finishes typical of milled channels

and another three square channels had internal longitudinal fins. A high heat flux test facility capable of handling cryogenic temperatures, developed for the purpose of simulating the high heat load conditions representative of regeneratively cooled rocket engines, was used in this study. Subcooled film-boiling phenomena were discovered for all the channels tested in this study. Film-boiling onset at critical heat flux correlated with the boiling number  $Bo \sim 0.1$ . The convective Nusselt number followed predicted trends for Reynolds numbers with a wall temperature correction for both the boiling and non-boiling regimes.

A test apparatus has been specifically designed for the purposes of investigating methane heat transfer behavior inside rocket engine cooling channels [172]. The apparatus was composed of a copper-alloy block warmed up by cartridge heaters and of a single channel with rectangular cross section, which was fed with a trans-critical methane flow. Steady-state conditions and channel dimensions were representative of a typical rocket engine cooling channel. Several tests have been conducted with mass flow rates ranging from 10 to 25 g/s, exit pressures from 60 to 150 bar, and inlet temperatures of about 130–140 K. The maximum provided heat flux at the bottom of the channel was  $20 \text{ MW/m}^2$ . Measurements of the channel inlet and exit temperature and pressure, mass flow rate, and wall temperature at different channel locations have provided useful data for the evaluation of heat transfer and pressure loss. In particular, the channel surface roughness induced by the manufacturing process has been estimated and a peculiar Nusselt number correlation has been obtained. This correlation was suitable for describing the thermal behavior of the rectangular cooling channel, including both methane flow and wall.

Methane heat-transfer deterioration can occur in the regenerative cooling channels of LOX/LCH<sub>4</sub> rocket engines with chamber pressures higher than about 50 bar. Aiming to improve the prediction capabilities for the design of cooling systems, a Nusselt number correlation able to describe the convective heat-transfer characteristics of supercritical flow exhibiting deterioration and with negligible buoyancy effects was derived using data from numerical simulations [173]. The adopted numerical solver of the Navier-Stokes equations was first validated against experimental data of near-critical hydrogen in heated tubes and then used to collect heat-transfer data of supercritical methane in a heated tube for different levels of pressure, temperature, and mass flux.

If a cryogenic fluid is used in the cooling jackets of a rocket engine, the coolant may behave as a trans-critical fluid: it may be injected as a liquid and, depending on the heat exchanged with the thrust chamber hot gases, may experience a pseudo-phase change. Finally, it comes out and is sent to the combustion chamber, located downstream, as a supercritical vapor. A breadboard test apparatus was equipped with a rectangular single channel, characterized by dimensions representative of typical rocket engine cooling channels [174]. Inlet temperature and pressure values, ranging from about 120 to 140 K, and from about 10 to 17 MPa respectively were varied one step at a time. A three-dimensional model, including inlet and outlet interfaces showed

very low discrepancies when compared with experimental data. Simulations enabled the description of the thermal stratification as well as the “thermal deterioration” of methane inside a cooling jacket-like channel under supercritical conditions.

A 3D fluid-structural coupled computational methodology was developed to predict the thermal and structural responses of the thrust chamber wall in a LOX/LCH<sub>4</sub> rocket engine under cyclic operating conditions [175]. The thermal and mechanical loads were determined by a validated 3D finite volume fluid-thermal coupled computational method. With the specified loads, a non-linear thermal-structural finite element analysis was applied to obtain the 3D thermal and structural responses.

A study of the non-uniform flow and heat transfer of supercritical cryogenic methane in a heated horizontal circular tube indicated that the peak value of the heat-transfer coefficient appeared near the vicinity of the pseudo-critical point [176]. The Reynolds number monotonically increased with the increase in bulk fluid temperature. However, the Prandtl number exhibited both peak and minima values. Compared with mass fluxes, operating pressures had less of an influence on the heat-transfer performance. Flow stratification phenomena and lateral secondary flows were developed as a result of the combined interaction of buoyancy and gravity. The “flow acceleration” caused by the variation of bulk fluid density had an important effect on the decrease in heat-transfer capacity. Further analysis demonstrated that the Blasius and Han models were able to predict the pressure drop and heat transfer of supercritical cryogenic methane.

Thermal behavior and heat-transfer deterioration of trans-critical methane as well as the fluid state change in regenerative cooling with straight or curved rectangular channels were studied numerically [177]. Simulations were conducted with a finite-volume based CFD solver utilizing reliable turbulence models and thermo-fluidic relations in trans-critical conditions. The known experimental and numerical results of hydrogen inside a heated tube reported in the literature were used for validation of the model. The effects of mass flow rate, outlet pressure, wall temperature, surface roughness, and the channel geometry on the thermal behavior of the coolant fluid were studied in detail. According to the results, variations in the slope of the transport property curves and the inflection point in the density distribution of the coolant flow were proposed as criteria for the recognition of the heat-transfer deterioration and trans-critical regions respectively. The outlet pressure and surface roughness had negligible effects on both methane heat transfer deterioration and trans-critical regions in contrast to the channel curvature, mass flow rate, and wall temperature.

The conjugate heat transfer of liquid methane coolant inside a rectangular channel was studied and the related Nusselt correlations were improved [178]. The compressible methane flow was assumed to enter the cooling channel at supercritical pressure and subcritical temperature such that the coolant flow absorbs heat from the heated walls and exits the channel with a supercritical temperature. An equation solver was developed employing a Semi-Implicit Method for Pressure-Linked Equations-Consistent algorithm accompanied by the appropriate thermodynamic

and transport property relations for the supercritical conditions of the methane coolant. The solver was validated with the experimental data found in the open literature. The behavior of pseudo-critical temperature and density versus pressure were studied and new relations were proposed. The accuracy of different Nusselt relations for estimating the heat-transfer coefficient of methane at supercritical pressures was evaluated. The variation of thermo-fluidic parameter correction factors (i.e., non-dimensional density, temperature, isobaric-specific heat, viscosity, and thermal conductivity) through the cooling channel was investigated. The current Nusselt relations were developed, and improved correlations were proposed for methane at the supercritical pressure inside a rectangular channel. The accuracy of the modified correlations was studied at different outlet pressures, heat transfer rates, and mass flow rates.

The effect of surface roughness on liquid methane ( $\text{LCH}_4$ ) convective heat transfer performance of traditionally and additively manufactured rocket engine cooling channels was studied by conducting high heat flux methane convective cooling tests using a diagnostic system designed and developed to investigate the steady-state heat transfer of cryogenic propellants [179]. This facility was designed to measure the one-dimensional and asymmetric heat flow performance as experienced in regeneratively cooled liquid rocket engine cooling channels. The experiments were performed under the influence of internal forced convection to better simulate the boiling performance in a rocket engine's environment. A total of four samples made of Inconel 625 were tested. Square channels with a cross-section of  $3.2 \times 3.2$  mm and various roughness values were fabricated using conventional milling and advanced 3D printing technologies. Some findings between the experimental Reynolds number and Nusselt number showed that the channels with the  $3.2\text{-}\mu\text{m}$  and  $6.3\text{-}\mu\text{m}$  roughness did not differ significantly in comparison with the smoothest channel ( $0.8\text{-}\mu\text{m}$ ). An increase in heat transfer of more than 100% could be observed with the roughest channel ( $12.5\text{-}\mu\text{m}$ ) during the convective subcooled flow of methane.

### 2.1.12 Critical Constants of Methane

Critical-point measurements reported by various sources are summarized in Table 18.

**Table 18:** Critical point conditions of methane.

| Critical temperature  |              | Critical pressure      |                    | Critical volume | References |
|-----------------------|--------------|------------------------|--------------------|-----------------|------------|
| SI units              | Other units  | SI units               | Other units        | SI units        |            |
| $190.6 \pm 0.3$ K     | $-82.55$ °C  | $46.1 \pm 0.3$ bar     | $45.5 \pm 0.3$ atm | —               | [45]       |
| 190.53 K              | $-82.62$ °C  | 4.596 MPa              | 45.356 atm         | —               | [180]      |

### 2.1.13 Solubility and Miscibility of Methane

#### 2.1.13.1 Pressurant Gas Solubility

Liquid methane is usually pumped from the propellant tanks into the rocket engine by turbo pumps and not pressure-fed. However, the tanks need to be pressurized with hot methane or an inert gas to provide sufficient net positive suction head to prevent cavitation in the inlet portion and on the blade tips of the pumps. The only gas suitable for the pressurization of liquid methane is helium.

The solubility of helium in liquid methane, liquid hydrogen, and liquid oxygen was described by empirical correlations derived from published experimental data for the mol fraction of these pressurant gases in the liquid phase as a function of temperature and pressure [181]. The correlations were developed to yield accurate estimates of the mol fraction of the pressurant gas in cryogenic liquids at temperature and pressures of interest to rocket propulsion engineers. The helium solubility correlations were of the form

$$\chi = p^* \exp(a + bp^*)$$

where  $\chi$  is the mol fraction solubility of the solute (helium) in the solvent liquid,  $p^*$  is a dimensionless pressure defined as  $p^* = (P - P_0)/P_{\text{REF}}$ , where  $P$  is the total pressure (from the pressurant gas and the vapor pressure of the liquid),  $P_0$  is the saturated vapor pressure of the pure liquid solvent at temperature  $T$ ,  $P_{\text{REF}}$  is a reference pressure defined as equal to 1 MPa, and  $a$  and  $b$  empirically determined, temperature-dependent functions. The coefficient  $b_0$  was determined from the isotherms to be  $b_0 = -0.015$ . For  $b = 0$ , the equation assumes the form of Henry's law. In a graph showing the mol fraction  $\ln(\chi/p^*)$  as a function of pressure for nine different temperatures between 93.2 and 173.2 K, the curves are linear and almost level, indicating minimum dependence of  $\chi$  on pressure. A graph showing the mol fraction  $\ln(\chi/p^*)$  as a function of temperature demonstrated an almost linear increase of  $\ln(\chi/p^*)$  with temperature. More specifically, the equation for the temperature dependence of  $\chi$  based on empirical data becomes

$$\chi = p^* \exp(-13.76 + 0.0748 \times T/\text{K} - 0.000137 \times T^2/\text{K}^2 - 0.015p^*)$$

where the terms in parentheses need to be divided by kelvin and kelvin<sup>2</sup> to make them dimensionless. The helium mol fraction solubility in liquid methane is less than 0.3% in typical propulsion system applications, and the times to reach equilibrium are very long in the absence of active mixing. Considering as an example a tank at the normal boiling point temperature of liquid methane, 111.5 K, and a total pressure of 1.72 MPa (250 psia,  $p^* = 1.62$ ), the equilibrium mol fraction solubility calculated from the above equation is  $\chi = 0.13 \pm 0.006\%$ .

The solubilities of oxygen, argon, carbon monoxide, nitrogen, neon, hydrogen, and helium in liquid methane at temperatures between 90 and 112 K were measured and expressed in logarithmic equations [182]. The solubilities of these gases in liquid methane decrease in the order in which they are listed. The rates of solution of gases

in liquefied natural gas are very high. Only the least soluble gases, neon, hydrogen, and helium, can be used as fuel system pressurants if liquefied natural gas is to be used in aircraft or rockets.

Oxygen, which has a normal boiling temperature of 90 K, would continuously condense in, and be miscible with, liquid methane in all proportions, with liquid methane maintained at 90 K. In a study of the solubility of methane in liquid oxygen, it was concluded that these formed a near-ideal solution at 90 K. Such mixtures, although detonable, have been proposed as monopropellants.

Helium dissolved and saturated in liquid methane may be released as bubbles when the pressure is suddenly lowered and bubbles and two-phase flow interfere with flow rate measurements. The kinetics of the spontaneous boiling of liquid methane saturated with helium has been studied in experiments on measuring the lifetime of the superheated liquid [183]. The temperature dependence of nucleation frequency  $J$  has been determined in a range from  $10^4$  to  $10^8 \text{ s}^{-1} \text{ m}^{-3}$  at pressures of  $P = 1.6$  and  $2.0 \text{ MPa}$  and helium concentrations in liquid methane  $\chi = 0.06$  and  $0.10 \text{ mol-}\%$ . The experimental results were compared with the data of the classical nucleation theory. As in the case of pure methane, the solution superheating temperatures reached in the experiments at  $J > 4 \times 10^6 \text{ s}^{-1} \text{ m}^{-3}$  appeared to be systematically lower (by  $0.6\text{--}1.0 \text{ K}$ ) than their theoretical values. It was shown that the discrepancy between the theoretical and experimental data is associated with the size dependence of the surface tension at the critical bubble-solution interface. See also Sinor [184] and Heck and Hiza [185].

One might also consider hydrogen as a pressurant gas for liquid methane, but it is more soluble than helium [186, 187]. The solubility of helium in liquid methane at 90.3 and 106 K was measured at pressures up to 160 atm. The helium solubility passed through a maximum of 2.7, 5.5, and 6.9 MPa (400, 800, and 1000 psia), within the range of temperatures studied.

### 2.1.13.2 Diluent and Contaminant Solubility

Some nitrogen may be carried over from the production and liquefaction plant and remain dissolved in liquid methane [55]. The specification MIL-PRF-32207 allows 100 to 5000 ppm of nitrogen in the methane, depending on which purity grade is required.

Moisture in methane may precipitate as ice crystals and clog orifices and filter screens. The unexpectedly high solubility of  $\text{H}_2\text{O}$  in liquid methane ( $6.0 \times 10^{-5} \text{ mol}$  fraction) at its normal boiling point of 112 K was determined by using Fourier transform infrared (IR) spectroscopy [188]. The possibilities of experimental artefacts were eliminated via parallel experiments with  $\text{D}_2\text{O}$ . Methane is known to form hydrates at a high pressure, such as at the bottom of oceans. The specification MIL-PRF-32207 limits the allowable moisture content in methane gas to 0.5 to 1 ppm by volume.

### 2.1.14 Thermodynamic Properties of Methane

The thermodynamic properties of methane have been thoroughly investigated for almost a century and are referenced in numerous table works. Most of the published data are for gaseous methane and only relatively few data are for liquid or even solid methane [88, 189, 190].

Thermodynamic properties of methane were described in terms of an equation of state for the real fluid together with an empirical equation for the specific isochoric heat capacity of the ideal gas [92]. The equation of state had a form proposed by Bender with coefficients refitted to precise measurements. In the fluid state for temperatures from 90.68 K (triple-point temperature) to 625 K, densities below 0.46 kg/dm<sup>3</sup> (2.8 times critical density) and pressures below 500 bar, thermodynamic properties of methane were predicted to high accuracy, as shown by comparison with reliable experimental data. Only in the critical region was the accuracy slightly lower. Several equations for the calculation of thermodynamic properties were presented. A comprehensive table was included of the following properties thus calculated at the vapor-liquid coexistence boundary and in the homogeneous region: specific volume, specific enthalpy, specific entropy, velocity of sound, isentropic exponent, and fugacity.

The equation of state and heat capacity of methane were determined at temperatures from 148 to 298 K with pressures up to 1000 MPa following a new computational method [191]. This method was based on the stepwise construction of  $p$ - $T$  isochores starting from an experimental reference  $p$ - $p$  isotherm and using sound speeds in methane as a function of pressure and temperature, together with the experimental heat capacity data of methane at lower pressures. In the region of overlap, the calculated  $\rho p T$  data were found to be in good agreement, namely within 0.08%, with those obtained previously from the most accurate direct measurement reported in the literature.

#### 2.1.14.1 Heat Capacity of Methane

##### Heat Capacity of Liquid Methane

Only a few laboratories have published experimental measurements of heat capacities of methane in the saturation state. The experimental data of the heat capacity along the saturated liquid curve  $C_\sigma$  and of the heat capacity  $C_p$  are summarized in Table 19. The measured data for the isobaric heat capacity of liquid methane are listed in Table 20.

Figure 19 illustrates the heat capacity  $c_p$  of liquid and gaseous methane under saturation pressure conditions. The heat capacities of liquid and gaseous methane are very similar and both increase abruptly as the temperature approaches the critical temperature.

Specific heats of the liquid phase, along the coexistence (saturation) path, are useful for computing thermodynamic properties in compressed liquid states. Data for

**Table 19:** Summary of experimental data for the heat capacity of methane on the saturated liquid line.

| 173.15           | 6.45            | 4.424                               | 1.057                               | 70.974                              | 16.963                                |

<sup>a</sup> Standard uncertainties  $u$  are  $u(T) = 0.5$  K for  $T < 220$  K,  $u(T) = 0.25$  K for  $T > 220$  K,  $u(p) = 35$  kPa, and combined expanded uncertainty  $Uc(c_p) = 0.02 \cdot c_p$  with a 95% level of confidence.

Data source: [194]

$C_\sigma$  were derived from observations on the two-phase, liquid-vapor system at constant volume by use of accurate PVT data for the two phases (Goodwin [69]). The data were shown in coordinates of  $C_\sigma u^e$  versus  $T$ , the weighted form used for least squares determination of coefficients in

$$C_\sigma = a + bu + \frac{c}{u^e}$$

**Figure 19:** Heat capacity  $c_p$  of liquid and gaseous methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

where  $C_\sigma$  is the heat capacity in  $\text{J mol}^{-1}\text{K}^{-1}$ ,  $u$  is the reduced temperature  $(T_c - T)/(T_c - T_t)$ , and  $a$ ,  $b$ ,  $c$ , and  $\epsilon$  are constants:

$$a = 29.250$$

$$b = 5.560$$

$$c = 18.924$$

$$\epsilon = 0.55.$$

### Heat Capacity of Gaseous Methane

The ideal gas heat capacity can be derived from statistical mechanical models based on spectroscopic data. The constant pressure heat capacity of methane gas at 298.15 K and 1 bar is  $35.69 \text{ J mol}^{-1}\text{K}^{-1}$ . The gas phase heat capacity of methane as a function of temperature can be calculated from a Shomate equation

$$C_p^\circ = A + B\tau + C\tau^2 + D\tau^3 + \frac{E}{\tau^2}$$

where  $C_p$  is the heat capacity in  $\text{J mol}^{-1}\text{K}^{-1}$  and  $\tau$  is the temperature in kelvin divided by 1000 [45]. The constants A through E are listed in Table 21 for two different temperature ranges.

Isobaric heat capacity data of methane were measured, giving 58 data points within the ranges 121–251 K and 3.2–5 MPa [195].

**Table 21:** Constants for methane gas thermodynamic data calculations.

| Temperature range, K | 298–1300  | 1300–6000 |
|----------------------|-----------|-----------|
| A                    | −0.703029 | 85.81217  |
| B                    | 108.4773  | 11.26467  |
| C                    | −42.52157 | −2.114146 |
| D                    | 5.862788  | 0.138190  |
| E                    | 0.678565  | −26.42221 |
| F                    | −76.84376 | −153.5327 |
| G                    | 158.7163  | 224.4143  |
| H                    | −74.87310 | −74.87310 |

Data source: [45]

### 2.1.14.2 Heat of Combustion of Methane

Literature values for the upper heat of combustion of methane are summarized in Table 22. Heat of combustion data for methane from various sources agree fairly well. This is a well-established procedure. See also [196].

**Table 22:** Upper heat of combustion of methane gas.

| SI units             | Other units            | References |
|----------------------|------------------------|------------|
| 890.71 ± 0.38 kJ/mol | 212.88 ± 0.09 kcal/mol | [197]      |
| 890.35 ± 0.30 kJ/mol | 212.80 ± 0.07 kcal/mol | [198]      |
| 891.8 ± 1.1 kJ/mol   | 213.14 ± 0.26 kcal/mol | [199]      |
| 890.16 ± 0.30 kJ/mol | 212.75 ± 0.07 kcal/mol | [200]      |

### 2.1.14.3 Enthalpy of Formation of Methane

Enthalpy of formation data of methane in various physical states are summarized in Table 23.

**Table 23:** Enthalpy of formation of methane.

| Physical state | SI units               | Other units       | References |
|----------------|------------------------|-------------------|------------|
| Gas            | −74.8731 kJ/mol        | −17.895 kcal/mol  | [201]      |
|                | −74.48 ± 0.42 kJ/mol   | −17.80 kcal/mol   | [197]      |
|                | −74.848 ± 0.314 kJ/mol | −17.889 kcal/mol  | [198]      |
|                | −73.39 ± 1.09 kJ/mol   | −17.54 kcal/mol   | [199]      |
|                | −74.6 ± 0.3            | −17.83 kcal/mol   | [202]      |
| Liquid         | −85.31 kJ/mol          | −1271 cal/g       | [203]      |
|                |                        | = −20.39 kcal/mol |            |
|                | −89.233 kJ/mol         | −21.327 kcal/mol  | [204]      |

Molecular mass: 16.0425 g/mol; 62.3344 mol/kg

The standard enthalpy of methane gas as a function of temperature can be calculated from the equation

$$H^\circ - H^\circ_{298.15} = A\tau + \frac{B\tau^2}{2} + \frac{C\tau^3}{3} + \frac{D\tau^4}{4} - \frac{E}{\tau} + F - H$$

where  $H^\circ - H^\circ_{298.15}$  is the differential standard enthalpy in kJ/mol and  $\tau$  is the temperature in kelvin divided by 1000. The constants A through H are listed in Table 21 above.

The enthalpy-pressure behavior for methane in the vapor phase was determined with a method based on measurements of the Joule-Thomson throttling effect [205]. Data were measured along six isotherms at 224, 247.50, 273.15, 298.15, 333.25, and 366.70 K. The experimental data and derived enthalpies were represented as polynomial functions of pressure up to a maximum of 100 bar. The enthalpy values were believed to be precise to within 5 J/mol. Comparisons were made with the calorimetric data of Jones et al., the derived enthalpies from the equation of state of Vennix et al. [59, 72] and the values calculated by Harrison et al. [206] from the accurate PVT data of Douslin et al. [73].

#### 2.1.14.4 Enthalpy of Vaporization of Methane

Enthalpy of vaporization data for methane are summarized in Table 24.

**Table 24:** Enthalpy of vaporization of methane.

| Temperature                    |         | Enthalpy of vaporization |          |       | References |
|--------------------------------|---------|--------------------------|----------|-------|------------|
| K                              | °C      | kJ/mol                   | kcal/mol | J/g   |            |
| 111.7 K (normal boiling point) | -161.4  | 8.17                     | 1.953    | 509.3 | [207]      |
| 112                            | -161.1  | 8.2                      | 1.960    | 511.1 | [50]       |
| 130                            | -143.1  | 7.5                      | 1.793    | 467.5 |            |
| 160                            | -113.1  | 5.9                      | 1.410    | 367.8 |            |
| 180                            | -93.1   | 4.0                      | 0.956    | 249.3 |            |
| 90.66                          | -182.44 | 8.661                    | 2.070    | 539.9 | [69]       |
| 110                            | -163.1  | 8.260                    | 1.974    | 514.9 |            |
| 99.54 ( $P = 2.81$ kPa)        | -173.6  | 8.519                    | 2.036    | 531.0 | [45]       |

Molecular mass: 16.0425 g/mol; 62.3344 mol/kg

The enthalpy of vaporization of methane at the saturation pressure as a function of temperature within the temperature range 112–180 K can be calculated from the equation

$$(\Delta H)^\circ_{\text{evap.}} = A \exp(-\alpha T_r)(1 - T_r)\beta$$

where  $(\Delta H)^\circ_{\text{evap}}$  is the enthalpy of vaporization in kJ/mol,  $T_r$  is the reduced temperature  $T/T_c$ , and  $T_c$  is the critical temperature in kelvin ( $T_c = 190.6 \text{ K}$ ). The constants are  $A = 10.11$ ;  $\alpha = -0.22$  and  $\beta = 0.388$ .

The enthalpy of vaporization derived from the Clapeyron equation was calculated, tabulated, and graphed for temperatures between 90.66 and 190 K (Figure 20) [69]. The enthalpy of vaporization drops to zero as the temperature approaches the critical point.

**Figure 20:** Enthalpy of vaporization of methane. (Reproduced and modified from [69].)

See also [54]. The entropy of vaporization at 99.54 K is  $85.58 \text{ J mol}^{-1} \text{ K}^{-1}$ . The enthalpy of sublimation of solid methane based on data from 53 to 91 K is  $9.7 \text{ kJ/mol}$  at 72 K [70].

#### 2.1.14.5 Entropy of Methane

The standard entropy of methane gas at 1 bar is  $186.25 \text{ J mol}^{-1} \text{ K}^{-1}$ . The entropy of methane as a function of temperature can be calculated from the equation

$$S^\circ = A \ln(\tau) + B\tau + \frac{C\tau^2}{2} + \frac{D\tau^3}{3} - \frac{E}{2\tau^2} + G$$

where  $S^\circ$  is the standard entropy in  $\text{J mol}^{-1} \text{ K}^{-1}$  and  $\tau$  is the temperature in kelvin divided by 1000. The constants A through G are listed in Table 21.

#### 2.1.15 Molecular Orbital Calculations of Methane

Theoretical thermodynamic properties of methane in the dense gas and liquid states have been calculated by the method of molecular dynamics [208]. The methane pair interactions were modelled using a spherically symmetric m-6-8 potential, and the most significant three-body and quantum effects were included. Agreement between calculated and experimental values for the energy and pressure was generally good

except at low temperatures and high densities. It was not certain if this method could also be used to predict the specific heat at constant volume.

## 2.1.16 Optical, Electrical, and Magnetic Properties of Methane

### 2.1.16.1 Infrared Absorption Spectra of Methane

The gas phase IR absorption spectrum of methane is shown in Figure 21.

**Figure 21:** Infrared absorption spectrum of methane. (Reproduced and modified with permission from [204].)

### 2.1.16.2 Index of Refraction of Liquid Methane

The refractive index of gaseous and liquid methane was measured between 95 and 300 K and at pressures of up to 225 bar (1 bar = 105 Pa) [209]. The measurements were performed at the  $^{198}\text{Hg}$  vapor green line,  $\lambda = 546.2\text{nm}$ , with a Fabry-Perot interferometer referred to vacuum. The refractive index data were combined with the previously measured densities of methane to calculate the Lorenz-Lorentz (LL) function. Refractometric virial coefficients were obtained from analysis of the small ( $\sim 0.5\%$ ) maximum exhibited by the LL function with increasing density.  $B_R$ , the second refractometric virial coefficient, was estimated to be  $\sim 6.0\text{ (cm}^3/\text{mol)}^2$  and was almost independent of temperature between 220 and 300 K. The critical-point refractive index,  $n_c = 1.10333$ , was extrapolated from a rectilinear diameter treatment of the saturated liquid and vapor results. The critical-point refractive index was combined with an estimate of the critical-point (LL) function to yield a critical density of methane,  $\rho_c = 10.16 \pm 0.01\text{ mol/L}$ . The measurement of the refractive index can be used to determine values of density and compressibility [107].

Comprehensive refractive index measurements  $n(P,T)$  were carried out on pure methane in the temperature range from 273 to 373 K and at pressures up to 34 MPa [210]. Two coupled laser interferometers were used for the experiments, one containing methane, the other the reference gas nitrogen maintained at the same pressure and a fixed temperature  $T_o$ , serving as a manometer. The uncertainty of the refractive index was estimated to be less than  $\pm 5 \times 10^{-7}$  at 1 MPa and  $\pm 5 \times 10^{-6}$  at 34 MPa. To measure the higher-order refractivity virial coefficients  $B_R$ ,  $C_R$ , of the

LL expansion, overflow experiments were made on the 323 K isotherm at pressures up to 35 MPa. Within the investigated range of pressure,  $B_R$  and  $C_R$  were the only significant refractivity virial coefficients. A comparison with literature values showed that  $B_R$  and  $C_R$  were independent of temperature within the range 220 to 373 K. On the basis of these  $n(P, T)$  measurements, the density was calculated by including  $B_R$  and  $C_R$ . The uncertainty of the density was estimated to be not greater than  $\pm 0.05\%$ .

### 2.1.17 Dielectric Constant of Liquid Methane

The dielectric constant of liquid and gaseous methane under conditions of saturated pressure is illustrated in Figure 22.

**Figure 22:** Dielectric constant of methane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

## 2.2 Chemical Properties of Methane

### 2.2.1 Reactions of Methane

The primary chemical reactions of methane that are of industrial significance are combustion, steam reforming to syngas, and halogenation for solvents and refrigerants. Attempts have been made to convert methane gas directly to the more storable methanol, but so far the only industrial methane-to-methanol conversion method is by way of syngas.

### 2.2.1.1 Oxidation Reactions of Methane

Methane combustion is the key reaction to using the energy from natural gas in a variety of applications, from home heating furnaces to industrial glass and steel melting furnaces to LNG-driven automobiles and, eventually, rockets.

Partial oxidation of methane to methanol is difficult because the reaction typically progresses all the way to carbon dioxide and water even with an under-stoichiometric supply of oxygen. There have been many attempts to perform a partial oxidation of methane without detracting too much from its heating value, for instance, by converting methane at remote gas wells to methanol that would be easier to store and transport to locations where energy is needed. These efforts have not yet resulted in an economical path to using methane from remote locations that is often flared off because there is no other use for it. Converting methane to synthesis gas and then performing Fischer-Tropsch synthesis resulting in more useful products is done in only a few locations in the world (e.g., Sasol in South Africa).

### 2.2.1.2 Kinetics of Methane Oxidation Reactions

In an effort to advance methane rocket propellant technology, quite often, existing rocket engines originally qualified for operation on kerosene or liquid hydrogen have been converted to operate on methane, although none of those has actually flown in a booster or upper stage. It is important to understand the difference in kinetics between kerosene combustion and methane combustion when designing a LOX/LCH<sub>4</sub> engine. The kinetics of LOX/methane combustion determine the required L\* of a LOX/LCH<sub>4</sub> engine required to achieve complete combustion before the propellant leaves the combustion chamber.

Because the reaction of gaseous oxygen and gaseous methane mixtures is often too fast, frequently transitioning into a detonation, most academic kinetic studies of the O<sub>2</sub>/CH<sub>4</sub> reaction have worked with diluents to slow down the reaction. Diluents often used are inert, non-reactive gases such as helium or argon. Even nitrogen as a diluent may already alter the results of such kinetic studies.

In addition to LOX/LCH<sub>4</sub> and GOX/GCH<sub>4</sub> reaction studies, there are also a multitude of air/CH<sub>4</sub> combustion kinetics studies where nitrogen is sometimes not just a diluent but also a participant in reactions. There are about 50 times more air/CH<sub>4</sub> combustion studies than undiluted O<sub>2</sub>/CH<sub>4</sub> combustion studies, but it is the latter mode of operation that is of interest for the rocket designer.

A comparison of three kinetic mechanisms, Leeds, GRI 3.0, and RAMEC, was made in an effort to find a kinetic model equally suitable for Rocket-Based Combined Cycle (RBCC) engines operating on LOX/LCH<sub>4</sub> or ramjets operating on air/CH<sub>4</sub> [211]. The kinetics mechanism from Leeds was chosen for further usage. The main reasons for this choice were its comparable small size and the fact that its kinetic properties were based more on theoretical and experimental data and less on the simple fitting of data. Furthermore, the Leeds mechanism generally did a better job at predicting ignition delay, which is considered a key feature for rocket applications. In rocket mode, combus-

tion chamber pressure varies between 0.1 MPa during ignition initiation and about 6–10 MPa during steady-state operation. For an air-breathing mode operation (SCRAM-JET mode), the combustion chamber most likely experiences only minor pressure variations during ignition and steady state-operation, i.e., 0.1–0.2 MPa. A chemical model of  $\text{CH}_4$  combustion applicable for CFD simulations of processes in combustors should have between 8 and 12 chemical species. Such kinetic models are called global mechanisms. These models were to be used for predicting ignition delays and laminar flame velocities. The laminar flame velocity is the most important characteristic of a fuel and it can be measured more precisely than the ignition delay time. The experimental flame velocity data typically have errors that do not exceed 10%.

#### **2.2.1.3 Methane Hydrate Formation**

Methane hydrates (also known as methane clathrates) are solid cages of water molecules (ice) that trap single molecules of methane. Methane clathrates have been found in arctic permafrost and beneath the ocean floor within the gas clathrate stability zone, located at high pressures (1 to 100 MPa; the lower end requires a lower temperature) and low temperatures ( $<258\text{ K} = <15^\circ\text{C}$ ; the upper end requires a higher pressure). Methane clathrates can form from biogenic methane, thermogenic methane, or a combination of the two. These deposits are both a potential desirable source of methane fuel as well as a potential unwanted contributor to global warming when they are suddenly released. Solid methane clathrates from moisture in liquefied methane may clog filters and orifices.

#### **2.2.1.4 Combustion of Methane**

The combustion of methane, in particular, flame speeds of pre-mixed and diffusion flames in air or oxygen, will be discussed in a later volume on non-hypergolic bipropellant combinations.

### **2.2.2 Quality Control Specification for Methane**

Procurement by the US Government of methane for rocket applications is governed by Military Specification MIL-PRF-32207 – Propellant, Methane (also Notice 1) [212]. This specification covers two types (Type I: Gas, Type II: Liquid) and three purity grades, as indicated in Table 25.

### **2.2.3 Analysis of Methane**

Another specification for the gas chromatography (GC) analysis of natural gas is the ASTM D 1945 Standard Test Method for Analysis of Natural Gas by Gas Chromatography.

Table 25: Purity requirements for methane per MIL-PRF-32207.

| Component                                                       | Unit                   | Requirements |         |         | Analytical method                   |
|-----------------------------------------------------------------|------------------------|--------------|---------|---------|-------------------------------------|
|                                                                 |                        | Grade 1      | Grade 2 | Grade 3 |                                     |
| Methane assay                                                   | %Vol, min              | 98.7         | 99.9    | 99.97   | GC ASTM D 1945                      |
| Water                                                           | ppmVol, max            | 1            | 0.5     | 0.5     | Hygrometer or electrolytic analyzer |
| Oxygen                                                          | ppmVol, max            | 1            | 1       | 1       | Oxygen analyzer                     |
| Nitrogen                                                        | ppmVol, max            | 5000         | 100     | 100     | GC                                  |
| Carbon dioxide                                                  | ppmVol, max            | 125          | 50      | 50      | IR spectrophotometric at 14.95µm    |
| Other gaseous impurities (e.g.,<br>Ar, H <sub>2</sub> , He, Ne) | ppmVol, max            | 5000         | 125     | 125     | GC ASTM D 1945                      |
| Ethane (C <sub>2</sub> H <sub>6</sub> )                         | ppmVol, max            | 5000         | 500     | 100     | GC ASTM D 1945                      |

| Total volatile sulfur                                           | ppmVol, max            | 1            | 0.1     | 0.1     | ASTM D 6667                         |
| Non-volatile residue and<br>particulates                        | mg/L, max <sup>a</sup> | 10           | 1       | 1       | Gravimetric                         |

GC = gas chromatography.

<sup>a</sup> Applicable to Type II only.

## 2.2.4 Thermal Stability of Methane

### 2.2.4.1 Coke Deposition During Thermal Decomposition of Methane

Theoretical specific impulse, ignition kinetics, pyrolysis-cracking kinetics, and heat transfer calculations of methane or natural gas in combination with LOX or HTP, in comparison with other fuels such as liquefied petroleum gas, methanol, ethanol, or kerosene, indicated that there should be no soot or coke deposition in regenerative cooling channels of engines operating with methane at 100-atm chamber pressure, but methane entering at 150 K could possibly heat up to above critical-point conditions [213].

The catalytic effects of Inco 718, Inco 600, and A286 are responsible for thermal cracking of pure  $\text{CH}_4$  and may prevent their use as materials for nozzles and combustion chambers [214]. The thermal cracking of pure  $\text{CH}_4$  mechanism was analyzed theoretically and compared with experimental results. The initial temperature of  $\text{CH}_4$  thermal cracking and the coking caused by catalytic activity of the material candidate were explained.

### 2.2.4.2 Radiation Stability of Methane

The radiolysis of methane, presumed to exist in lakes on the moon Titan, under the influence of cosmic radiation, would result in formation of higher hydrocarbons and a tar-like polymer called tholin. It is unlikely that liquid methane stored in orbital propellant depots on Earth or Mars would suffer the same fate, because most of the radiation is shielded by the tank wall material. The radiolysis of methane and other hydrocarbons was already discussed in a previous section, Section 1.2.2.

## 2.3 Compatibility with and Corrosion of Materials in Methane

Experiments were performed in which electrically heated oxygen-free high thermal conductivity = OFHC copper tubes were exposed to flowing high-velocity methane fuels [215]. Significant corrosion was observed during these tests as indicated by recession of the inside tube walls. No corrosion was, however, observed from elevated temperature static exposures of copper specimens to high-pressure liquid natural gas (LNG) and high-purity methane fuels. Mechanisms postulated to explain this corrosion were: (1) sulfur embrittlement, (2) corrosion interactions with high AC currents, (3) erosion-corrosion, (4) electrochemical corrosion, (5) zeta corrosion, and (6) mercury corrosion.

Materials compatibility of hydrocarbon fuels (methane, Mil-Spec RP-1, *n*-dodecane, and propane) in contact with copper-based combustion chamber liner materials (oxygen-free high thermal conductivity = OFHC, NASA-Z, and ZrCu coppers) was tested using two different methods [216, 217]. Static tests, in which copper coupons were exposed to fuel for long periods at constant temperature

and pressure, provided compatibility data in a precisely controlled environment. Dynamic tests, using the Aerojet Carbothermal Test Facility, provided fuel and copper compatibility data under realistic booster engine service conditions. Tests were conducted using very pure grades of each fuel and fuels to which a contaminant, e.g., ethene (ethylene) or methyl mercaptan, was added to define the role played by fuel impurities. It was found that each of the copper materials exhibited similar compatibility behavior. However, there were significant differences among the various hydrocarbon fuels tested. In methane, no carbon deposits were formed up to  $T_{\text{wall}} = 774\text{ K}$  (934 °F) and copper corrosion was observed with sulfur contents down to 1 ppm. Copper(I) sulfide is the corrosion product. Severe corrosion of copper was observed when very small amounts of sulfur impurities (e.g., 1 ppm of methyl mercaptan) were added to the methane. There were subsurface gouges formed in the channel surface during a dynamic test with methane plus 1 ppm methyl mercaptan. In two tests conducted with a relatively high concentration of methyl mercaptan in the methane (200 and 10 ppm respectively) the formation of corrosion product ( $\text{Cu}_2\text{S}$ ) became so massive that it entirely blocked the flow of fuel through the channel.

Dynamic exposure tests using methane and NASA-Z copper test specimen under conditions that simulated those expected in the cooling channels of a regeneratively cooled LOX/hydrocarbon booster engine operating at chamber pressures up to 3000 psi showed that methane with less than 0.5 ppm sulfur contamination has little or no effect on cooling channel performance [218]. At higher sulfur concentrations, severe corrosion of the NASA-Z copper alloy occurred and the copper(I) sulfide  $\text{Cu}_2\text{S}$  layer thus formed impeded mass flow rate and heat transfer efficiency. It was recommended that the methane specification for this end use set the allowable sulfur content at 0.5 ppm (max). As of 1991, bulk high purity liquid methane that met this low sulfur requirement was available from only one producer. It was found that dilute sodium cyanide solutions effectively refurbish sulfur-corroded cooling channels in only 2 to 5 min by completely dissolving all the  $\text{Cu}_2\text{S}$ . Sulfur-corroded/sodium cyanide refurbished channels are highly roughened and the increased surface roughness leads to significant improvements in heat transfer efficiency, but only with an attendant loss in mass flow rate.

## 2.4 Safety Properties of Methane

Methane is non-toxic, an asphyxiant, but it is very flammable and may form explosive mixtures with air. Methane is an asphyxiant if the oxygen concentration in a methane-filled chamber is reduced to below about 16% by displacement [219]. Most people can tolerate a reduction of oxygen concentration from 21 to 16% without ill effects. The concentration of methane at which asphyxiation risk becomes significant is higher than the 5–15% concentration in a flammable or explosive air/methane mixture.

## 2.5 Environmental Effects of Methane

Somebody with the required background knowledge should write a book on the environmental effects of methane. It is unlikely that the increasing use of methane as a rocket propellant will change that assessment. Boiloff from liquid methane storage tanks at rocket launch sites can be flared.

## 2.6 Explosive and Fire Hazards of Methane

Methane emanates continuously from coal deposits underground, in particular wherever coal seams are penetrated with mine shafts and tunnels (galleries) during coal mining activities. Air/methane (“firedamp”) explosions in coal mines have caused thousands of fatalities. Various instruments have been developed to detect methane in the air in coal mines and provide advance warning of flammable conditions. Fire and explosion hazards associated with liquefied natural gas have been thoroughly investigated [220, 221].

### 2.6.1 Limits of Flammability of Gaseous Air/Methane Mixtures

The flammability limits of air/methane mixtures were investigated experimentally at pressures up to 5500 kPa and temperatures up to 473 K (200 °C) [222]. Two different criteria based on the maximum explosion pressure were used to define the flammability limit: the tangent criterion and the min-max criterion. It was shown that the min-max criterion should be used to determine the upper flammability limit (UFL), because the tangent criterion underestimates the UFL at initial pressures higher than ambient. Within the pressure-temperature range tested second-order pressure dependences and linear temperature dependences of the UFL were found. The temperature dependence of the UFL was influenced by the initial pressure, which was in contrast with previous findings.

The UFLs of air/hydrogen, air/methane, air/ethane, air/*n*-butane, and air/ethene (ethylene) were determined experimentally at room temperature (293 K = 20 °C) and initial pressures of 1.0, 0.7, 0.5, 0.3, 0.1, and 0.05 atm [223]. Experiments were conducted in a closed cylindrical stainless steel vessel with an internal diameter of 10 cm and a length of 100 cm with upward flame propagation. The UFL of hydrogen was observed to be inversely proportional to the initial pressure within the range 1.0 to 0.3 atm and proportional to the initial pressure from 0.3 to 0.05 atm. In contrast, the UFLs of the lower alkanes and ethene (ethylene) decreased with the initial pressure. The average flame propagation velocities at UFL concentrations of hydrogen, methane, ethane, *n*-butane, and ethene (ethylene) in air at reduced pressures were also examined. It was found that the flame propagation velocity of hydrogen was larger than those of

the hydrocarbons, increased when the initial pressure decreased from 1.0 to 0.3 atm, and then decreased with further a decrease in pressure. Flame propagation velocities at UFL concentrations of the hydrocarbons decreased with the initial pressure. In a parallel series of experiments, the lower flammability limits (LFLs) of air/hydrogen, air/methane, air/ethane, air/*n*-butane, and air/ethene (ethylene) were also measured in the same closed cylindrical vessel (inner diameter 10 cm, length 100 cm) under the same conditions with upward flame propagation, at room temperature (293 K = 20 °C) and initial pressures of 1.0, 0.7, 0.5, 0.3, and 0.1 atm [224, 225]. The LFL of hydrogen initially decreased with pressure from 1.0 to 0.3 atm, but then the LFL increased with a further decrease in pressure. In contrast, the LFLs of the hydrocarbons increased when the pressure decreased from 1.0 to 0.1 atm, except for methane, for which the LFL did not change with pressure. The adiabatic constant volume flame temperatures at the new measured LFL concentrations of hydrogen and the hydrocarbons were calculated at sub-atmospheric pressure conditions. The behaviors of the adiabatic flame temperatures of hydrogen and the hydrocarbons were similar to those of the LFLs under the influence of low pressures.

### 2.6.2 Minimum Ignition Energy of Methane in Air

The minimum ignition energy of stoichiometric mixtures of methane in air at room temperature and sea level pressure is 0.4 mJ. Expanding the measurements of minimum ignition energy to elevated temperatures and elevated pressures, the minimum ignition energy of air/methane mixtures by spark ignition was measured for different temperatures (303–423 K = 30–150 °C) and different pressures (0.1–0.9 MPa) [226]. The effect of gap width was measured for gap widths between 0.2 and 2.0 mm and the most efficient ignition was with a gap width of 1 mm. Results depended on the width of the electrode gap, which was normally 1 mm for the remainder of the tests. The methane equivalence ratio was maintained at 1.0 (stoichiometric for CO<sub>2</sub>). The minimum ignition energy at 303 K and 0.1 MPa was 0.49 mJ. This compares well with minimum ignition energies reported by earlier authors ranging from 0.28 to 0.50 mJ [227–230]. The minimum ignition energy decreased with increasing pressure or temperature. The minimum ignition energy had a high order exponential relationship with  $1/P^2$ , but an approximately linear inverse relationship with  $1/T$ . At room temperature, the minimum ignition energy decreased in accordance with the equation

$$\text{MIE} = 0.000928 + 0.00489/P^2$$

where MIE is the minimum ignition energy in mJ and  $P$  is the pressure in MPa. With increasing temperature, the influence of pressure on the MIE became less pronounced. The effect of the temperature on the MIE decreased with increasing pressure. See also [231, 232].

### 2.6.3 Spontaneous Ignition of High-Pressure Releases of Methane into Air

The spontaneous self-ignition of high-pressure jets of hydrogen gas released into air has been described in detail in *Encyclopedia of Liquid Fuels*, chapter “Hydrogen.” A similar mechanism may be responsible for spontaneous self-ignition of high-pressure jets of methane or natural gas into surrounding air [233].

### 2.6.4 Accidental Detonation of Gaseous Oxygen/Methane Mixtures

The controlled detonation of air/methane and oxygen/methane mixtures, which may be of interest for use in pulse detonation rocket engines, will be discussed in a later volume on non-hypergolic bipropellant combinations.

Here we are discussing only the hazards and safety aspects of accidental explosions of this type. Detonations may propagate in flowing oxygen/methane mixtures, but always faster than the unburnt gases can flow [234].

During a study of the venting of a fast flame (100–800 m/s) in a round ignition pipe (140 mm I.D.) into a semispherical vessel containing a mixture of the same composition and initial pressure, the flame jet emerging from the pipe interacted with the remains of an unburned starting ring vortex set into motion by the accelerating flame front, and the subsequent intense combustion led to the initiation of an unconfined detonation inside the vessel [235]. A parametric investigation of this phenomenon in nitrogen-diluted (29.4–68.4 vol.-%) stoichiometric mixtures of oxygen/propane has been carried out for a range of exit orifice diameters (50, 101, and 140 mm) under initial pressure of 0.4 and 1 atm. A small number of atmospheric pressure experiments have also been conducted with nitrogen-diluted (33.3–57.1 vol.-%) stoichiometric oxygen/methane mixtures. One criterion, based on the notion of a critical Damköhler number and minimum energy release requirement, has been suggested for the initiation of unconfined detonation by a venting jet flame. All experimental results for a given initial pressure and fuel may be combined into a single curve, separating conditions leading to detonation from those that do not. The critical orifice diameter below which a transition to unconfined detonation does not occur was reduced for a venting fast flame by comparison with a steady detonation wave.

## 2.7 Disposal of Methane

Surplus methane vented from fuel tanks and transfer lines during the initial filling with liquid methane and cooldown can be burned in flare stacks. The design of flare stacks for methane would be similar to those designed for disposal of gaseous hydrogen.

Surplus methane concentrations below the lower flammable limit may have to be destroyed in a thermal oxidizer (also known as thermal incinerator), which is a process unit for air pollution control in many chemical plants that decomposes hazardous

gases at a high temperature and releases them into the atmosphere, but requires additional natural gas to operate the combustion chamber.

## 2.8 Fuel Mixtures with Methane

Methane has been evaluated as a fuel in mixtures with numerous other hydrocarbons and physical properties have been determined, such as in mixtures with ethane, ethene, propane, or butane. There are no obvious advantages of methane/fuel mixtures as rocket fuels over the use of pure methane or liquefied natural gas by itself.

### 2.8.1 Fuel Mixtures of Methane with Ethane

Liquid methane and liquid ethane are miscible over the entire range of compositions. Ethane is the second-most common hydrocarbon constituent of natural gas and is frequently found in liquefied natural gas. The effects of uncontrolled amounts of ethane on the physical properties of methane must be known before one decides to remove ethane from natural gas, prior to using LNG instead of pure methane as a rocket propellant. Although the boiling points of the two hydrocarbons are 72° apart, it is difficult to separate them by simple distillation [236, 237].

Ethane may be added to methane on purpose in order to lower the freezing point and allow the fuel to be cooled to temperatures lower than pure methane and to be densified to densities higher than those possible with pure methane, allowing more fuel to be packed into the same tank volume. Similar methane mixtures with other lower *n*-alkanes also have lower freezing points [238]. A step-by-step variation of the freezing point in the paraffin homologous series was examined to provide reasonably accurate extrapolation of scattered freezing-point data on the methane/*n*-butane mixture to other paraffin hydrocarbon mixtures of methane in which the heavier constituent ranged from ethane to *n*-nonane, inclusive, illustrated in a composite graph of the freezing points of the various binaries with methane, from ethane to *n*-nonane.

Measurements of the thermal conductivity of mixtures of methane and ethane revealed an enhancement in the mixture-critical region, contradicting theoretical predictions [239]. The anomaly was similar in size and temperature dependence to that found for pure fluids.

The thermal conductivity surface for three methane-ethane mixtures with methane mol fractions of 0.69, 0.50, and 0.35 was defined by up to 13 isotherms at temperatures between 140 and 330 K, with pressures up to 70 MPa and densities up to 25 mol/L [240–242]. The measurements were made with a transient hot-wire apparatus covering a wide range of physical states, including dilute gas, single-phase fluid at temperatures above the maxcondentherm, compressed liquid states, and vapor at temperatures below the maxcondentherm. The results showed an enhancement

in the thermal conductivity in the single-phase fluid down to the maxcondentherm temperature, as well as in the vapor and in the compressed liquid.

Comprehensive isochoric ( $P$ ,  $V_m$ ,  $x$ ,  $T$ ) physical state values have been obtained for  $\{x\text{CH}_4 + (1-x)\text{C}_2\text{H}_6\}$  mixtures with  $x = 0.35, 0.50$ , and  $0.69$  at densities ranging from 1 to 25 mol/L [243]. The measurements for each composition covered a temperature range from approximately 100 to 320 K at pressures up to 35 MPa. For each mixture the results were fitted to a 32-term modified Benedict-Webb-Rubin equation of state, supporting further development of an extended corresponding-states model.

A method for predicting transport coefficients of binary molecular liquid mixtures has been verified by measuring the thermal conductivity of liquid methane-ethane mixtures [244].

Measurements of the molar heat capacity at constant volume  $C_V$  of  $\{x\text{CH}_4 + (1-x)\text{C}_2\text{H}_6$ ,  $x = 0.35, 0.50, 0.68\}$  mixtures at 100 to 320 K and at pressures up to 35 MPa were made on samples of constant mass contained by a calorimeter vessel of nearly constant volume [245]. Critical enhancement of heat capacity for each mixture was apparent in the critical-temperature region for constant density and similarly in the critical-density region for constant temperature. Liquid heat capacities at saturation, obtained by extrapolation at constant density, had a minimum for each composition occurring at twice the estimated critical density. Reduced configurational heat capacities at saturation, examined as functions of reduced density  $\rho/\rho_c$ , fell into a family of parallel curves that had minima at  $\rho/\rho_c = 2.0$ .

Velocity of sound data were measured for 13 binary mixtures and 4 multi-component mixtures of natural gas components using a cylindrical cavity over a temperature range from 250 to 350 K and at pressures up to 10 MPa [246]. The binary mixtures were primarily methane-rich, with ethane, nitrogen, carbon dioxide, or propane as the second component. The multi-component mixtures are representative of commercially available gas compositions in the United States and Europe. The data were used to develop and test mathematical models for prediction of the sound speed of natural gas mixtures, within an average uncertainty of 0.1%, over the ranges of pressure, temperature, and composition that encompass the major region of custody transfer for natural gas. This work covered only data for mixtures of  $\text{CH}_4/\text{C}_2\text{H}_6$ ,  $\text{CH}_4/\text{C}_3\text{H}_8$ , not for the pure compounds by themselves.

An equation of state for the thermodynamic properties of mixtures of methane and ethane in the critical region was developed that incorporated the crossover from singular thermodynamic behavior near the locus of vapor-liquid critical points to regular thermodynamic behavior outside the critical region [247]. The equation of state provided a sufficiently accurate representation of the thermodynamic property data for the mixtures within a wide range of temperatures and densities.

Thermal-conductivity measurements for an equimolar mixture of methane and ethane very close to the critical point confirmed that the thermal conductivity of

a mixture does not diverge at the vapor-liquid critical point but crosses over to a finite limiting behavior at the critical point [144]. An extension of the mode-coupling theory for dynamic critical phenomena in mixtures gave a good quantitative description of the experimental thermal conductivity data. The same theory enables one to predict other transport properties of the mixture in the vicinity of the critical point [145].

A single-cycle apparatus was used to measure vapor-liquid equilibrium data for the binary system ( $\text{CH}_4 + \text{C}_2\text{H}_6$ ) over low temperatures of (126 to 140) K and pressures up to 0.64 MPa [248]. The Peng-Robinson model with a modified Huron-Vidal mixing rule and a Wilson model were used to correlate the experimental data for the binary system, and the interactive parameters of the Wilson model were given. The model predicted satisfactory results over the range of experimental temperatures and pressure.

The capillary constant  $a^2$  of ethane-methane solutions was measured and the surface tension  $\sigma$  was calculated within the temperature range 93 to 283 K at pressures from that of saturated vapors of pure ethane to 4 MPa, leading to equations that approximated the temperature, pressure, and concentration dependences of  $a_2$  and  $\sigma$  [249]. The concentration dependence of the surface tension was described based on models of an ideal and a regular solution and the relative adsorption has been calculated.

A specialized cell designed for vapor liquid equilibrium measurements at cryogenic temperatures and high pressures was used to measure new ( $P, T, x, y$ ) data for binary mixtures of methane + ethane, methane + propane, methane + 2-methylpropane (*iso*-butane), and methane + butane from 203 to 273 K at pressures up to 9 MPa [250]. A literature review of vapor liquid equilibrium data for these binary mixtures indicated that a significant number have large uncertainties. However, because estimates of uncertainties in measured phase compositions are often not quantified sufficiently, it can be difficult for equation of state (EOS) developers to identify which data sets are of poor quality. Robust quantitative uncertainties were estimated for the vapor liquid equilibrium data acquired in this work, which allowed the identification of literature data sets that should not be included in future EOS development. The new data were compared with predictions of the Peng-Robinson EOS and the Groupe Européen de Recherche Gazière (GERG-2008) multi-parameter EOS.

Icy bodies in the outer Solar System such as Titan, the largest moon of Saturn, contain simple hydrocarbons, and methane and ethane interact with each other at low temperatures and Titan-like pressures. In mapping the methane-ethane system as a function of composition, it was shown that this is a eutectic system where the freezing point is depressed down to  $71.15 \pm 0.65$  K (whereas pure methane and ethane freeze at 90.56 and 90.09 K respectively), at a mix containing  $64.4 \pm 1.8\%$   $\text{CH}_4$  and  $35.6 \pm 1.8\%$   $\text{C}_2\text{H}_6$  [251].

### 2.8.2 Fuel Mixtures of Methane with Ethene

Fuel mixtures of methane with ethene,  $C_2H_4$ , have not yet been considered as rocket fuels. Mixtures of methane and ethene may be encountered in the products of cracking reactors in petroleum refineries.

The total vapor pressure of liquid mixtures of methane and ethene has been measured as a function of composition at 103.94 and 115.77 K and the results have been used to estimate the excess Gibbs energy at these temperatures [252]. The volume of mixing was determined at 103.94 K and was found to be small and negative. An attempt was made to estimate the value of the molar enthalpy of mixing. The results were interpreted in the light of some simple theories of mixtures, suggesting that this might be a case where the Lorentz rule of combination of collision diameters is valid.

### 2.8.3 Fuel Mixtures of Methane with Propane

Fuel mixtures of methane with propane have not yet been used as rocket fuels. Mixtures of methane with propane may be encountered in the off-gas from petroleum refining processes [54].

The viscosities and densities of methane-propane mixtures were determined at pressures up to 34.5 MPa (5000 psia) for 22.1 and 50.0 mol-% methane over a temperature range from 153 to 311 K (−120 to +37.78 °C) and for 75.3 mol-% methane over a temperature range from 123 to 311 K (−150 to +37.78 °C) [253]. Reproducibility of the viscosity data was  $\pm 2\%$ , and the agreement with literature values was, on average, within  $\pm 2\%$ . The reproducibility of the density data was  $\pm 0.8\%$ , and the agreement with literature values was  $\pm 1.2\%$ .

The total vapor pressure of liquid mixtures of methane and propane has been measured as a function of composition at temperatures of 115 and 135 K [65]. The activity coefficient of methane  $f_1$  and the excess Gibbs function of mixing  $\Delta G$  have been evaluated from the vapor pressure measurements, and the heat of mixing and the excess entropy of mixing have been estimated from the temperature dependence of  $\Delta G$  and compared with direct calorimetric values. Values of the excess thermodynamic functions have been calculated from a simplified version of the Flory theory of mixtures, with allowance for departures from the geometric mean (Berthelot) combining rule. Calculations showed that these deviations were very small, but not negligible.

Isobaric heat capacities  $c_p$  of  $CH_4 + C_3H_8$  mixtures at  $x_1 \approx 0.8$  and  $P \approx 5$  MPa and  $CH_4 + C_4H_{10}$  mixtures at  $x_1 = 0.96, 0.88, \text{ and } 0.60$  were measured at temperatures between 108 and 168 K for liquid mixtures and  $P \approx 5$  MPa [254]. Measurements were made using a specialized calorimeter further modified to prevent preferential condensation of the less volatile component and minimize possible stratification of the mixture during sample loading. Similar differences from the various equations of state were observed for the data of Furtado [255], who measured the  $c_p$  of a mixture with a mol fraction composition of  $0.359 CH_4 + 0.314 C_2H_6 + 0.327 C_3H_8$  at similar temperatures.

#### 2.8.4 Fuel Mixtures of Methane with Butane

Fuel mixtures of methane with butane have not yet been used as rocket fuels. Mixtures of methane with butane may be encountered in the off-gas from petroleum-refining processes. The boiling points of the two liquids are quite different; thus, it should be easy to separate them by distillation.

Bubble-point compositions for the methane-*n*-butane system were measured and combined with dew-point data to give K-values for the methane-*n*-butane system at 278, 255, 244, 233, 222, 211, 200, 190.6, 189, 178, 166, 155, and 144 K (40, 0, -20, -40, -60, -80, -100, -116.6, -120, -140, -160, -180, and -200 °F) from the vapor pressure of *n*-butane up to the critical point or the vapor pressure of methane [66]. Experimental conditions were selected so that direct isobaric observations were also possible.

Isobaric heat capacity measurements of mixtures of liquid methane and liquid butane were already described in the preceding section on methane-propane mixtures [254].

#### 2.8.5 Metal Slurries in Gelled Liquid Methane

The heat of combustion of liquid methane can be increased by suspending metal particles in the liquid methane. In order to prevent the metal particles from settling, the cryogenic liquid methane has to be gelled. It is very difficult to find gelling agents for cryogenic fuels.

### 2.9 Applications of Methane

There are numerous applications of methane as the fuel in rocket propulsion systems, mostly with LOX as the oxidizer. Theoretical performance calculations, design guidelines, and examples of flight applications for the LOX/LCH<sub>4</sub> combination will be provided in a future volume on non-hypergolic bipropellant combinations.

## 3 Ethane

Ethane, C<sub>2</sub>H<sub>6</sub>, CAS RN [74-84-0], is a common constituent of natural gas and is often associated with methane in the various applications of methane. Traces of ethane are not detrimental to the properties of methane as a rocket fuel.

### 3.1 Production and Availability of Ethane

After methane, ethane is the second most prominent constituent of natural gas. Natural gas from different gas fields varies in ethane content from less than 1 vol.-% to

more than 6 vol.-%. Ethane can be prepared by separating it from methane in natural gas by liquefaction and fractionated distillation or swing adsorption on molecular sieves. Ethane is forming lakes on Titan, the moon circling Saturn. Ethane (along with ethene) is formed in the cracking of oil crudes in petroleum refineries. The main use of ethane is to convert it to ethene for polyethylene polymer production. Ethane is unlikely to become a rocket fuel in its own right. It will ride along with methane, only slightly changing the properties of liquid methane, but a contaminant that has to be reckoned with if LNG instead of liquid methane is used as a rocket fuel.

The theoretical ideal work required for liquefaction of ethane starting at 300 K and 101.3 kPa is 353.1 kJ/kg (151.8 BTU/lb).

### 3.2 Physical Properties of Ethane

The physical properties of ethane have been summarized in several useful publications [94, 256, 257].

#### 3.2.1 Freezing Point of Ethane

The freezing point of ethane is at 89.2 K (−183.9 °C). The triple-point properties of ethane are summarized in Table 26.

**Table 26:** Triple-point properties of ethane.

|             |                                             |
|-------------|---------------------------------------------|
| $T_t$       | 90.348 K                                    |
| $P_t$       | $1.1308 \times 10^{-6}$ MPa                 |
| $\rho_{tL}$ | 21.680 mol/dm <sup>3</sup>                  |
| $\rho_{tV}$ | $1.5154 \times 10^{-6}$ mol/dm <sup>3</sup> |

Data source: [94]

#### 3.2.2 Boiling Point of Ethane

The boiling point of ethane is  $184.6 \pm 0.6$  K (−88.5 ± 0.6 °C).

#### 3.2.3 Density and Partial Molar Volumina of Liquid Ethane

The density and surface tension of liquid ethane was measured between 126 and 178 K, as listed in Table 27 [258].

#### 3.2.4 Equation of State for Ethane

A comprehensive study of pressure, volume, temperature relations for ethane included new experimental vapor pressures in relation to the critical, orthobaric

**Table 27:** Density and surface tension of liquid ethane.

| Temperature | Density           | Temperature | Surface tension |        |
|-------------|-------------------|-------------|-----------------|--------|

Data source: [258]

densities for the coexistence envelope, with critical constants ( $P_c = 4871.76$  kPa or 48.0807 atm,  $T_c = 305.33$  K,  $V_c = 0.14556$  dm<sup>3</sup>/mol, and  $\rho_c = 6.870$  mol/dm<sup>3</sup>), virial coefficients  $B_0$ ,  $C_0$ , and  $D_0$ , and compression factors  $Z = pV/RT$  in the compressed fluid to 400 atm and 623 K [259]. The effect of gravity on the density of near-critical fluids and the critical point was significant even for small fluid heights (2 cm). The diameter of the coexistence envelope,  $(p_1 + p_g)/2$ , had a gradual curvature at all temperatures up to the critical.

A formulation for the thermodynamic properties of the fluid phase of ethane in the form of a fundamental equation explicit in the Helmholtz energy was presented where the functional form of the residual part was developed using state-of-the-art linear and non-linear optimization algorithms [260]. It contained 44 coefficients that were fitted to selected data for the thermal and caloric properties of ethane both in the single-phase region and on the liquid-vapor phase boundary. The equation of state described the  $ppT$  surface of ethane with an uncertainty in density of less than 0.02–0.03% from the melting line up to temperatures of 520 K and pressures of 30 MPa. In the gaseous and supercritical region, high precision velocity of sound data were represented generally within less than 0.015%. Other reliable data sets were represented within their experimental uncertainties. The primary data, to which the equation was fitted, covered the fluid region from the melting line to temperatures of 675 K and pres-

tures of 900 MPa. Beyond this range, the equation showed reasonable extrapolation behavior up to very high temperatures and pressures.

### 3.2.5 Viscosity of Ethane

The shear viscosity coefficient of compressed gaseous and liquid ethane was measured at temperatures between 95 and 320 K and at pressures up to 30 MPa (4350 psia) with a torsionally oscillating quartz crystal viscometer [261]. The results of the measurements were compared with an equation previously proposed for calculating the viscosity of gaseous and liquid ethane. Differences between the equation and the measurements reported were less than 6%. The largest differences were found at low temperatures and high pressures, and along a supercritical isotherm at 320 K ( $T \approx 1.05T_c$ ).

A set of equations for the viscosity of ethane was based upon a body of experimental data that had been critically assessed for internal consistency and for agreement with theory in the zero-density limit, vapor phase, and critical region [262]. The equation extended over the temperature range from 100 K to the critical temperature in the liquid phase and from 200 K to the critical temperature in the vapor phase. In the supercritical region, the temperature range extends to 1000 K for pressures up to 2 MPa and to 500 K for pressures up to 60 MPa. The ascribed accuracy of the representation varies according to the thermodynamic state from  $\pm 0.5\%$  for the viscosity of the dilute gas near room temperature to  $\pm 3.0\%$  for the viscosity at high pressures and temperatures. Viscosity data generated by the equations at selected temperatures and pressures and along the saturation line were tabulated.

A vibrating-wire viscometer was used to measure the viscosity of gaseous ethane [263]. The experimental data were taken at subcritical temperatures of 290 and 300 K up to 88% of the saturated vapor pressure and at supercritical temperatures of 310, 320, 340, 370, 400, and 430 K at pressures up to a maximum of 30 MPa. The measured data were evaluated using an equation of state by Bücker and Wagner. The viscosity values of the isotherms were correlated as a function of reduced density using a power series expansion. A comparison with correlations from the literature showed deviations up to about 5% in the near critical region and up to 2% at higher densities and temperatures. On the basis of a comparison with direct experimental data from the literature, it was concluded that the new values are the most reliable for an improvement in the viscosity surface correlation of ethane. The measurements were later re-evaluated based on the determination of the wire radius using an improved calibration method [264].

An apparatus combining a vibrating-wire viscometer and a single-sinker densimeter was used to provide accurate  $\eta\rho pT$  data for four isotherms on ethane at 293, 307, and 423 K [265]. The maximum pressure was chosen to be about 95% of the saturated vapor pressure for the subcritical isotherms and a maximum of 30 MPa for the supercritical isotherms. Near the critical region, allocation errors for temperature and pressure have a significant impact on the uncertainty of the experimental densities. The

new viscosity data and additionally re-evaluated earlier data were compared with the viscosity surface correlations by others for ethane and propane as well as with selected experimental data for the low-density region. The new viscosity data should be used to improve the viscosity surface correlations available in the literature.

### 3.2.6 Surface Tension of Ethane

The surface tension of liquid ethane was measured between 129 and 180 K by a capillary rise method where three capillaries with different diameters (0.2, 0.4, and 2 mm) were interconnected and partially filled with liquid [258]. The data are summarized in Table 28.

**Table 28:** Surface tension of ethane.

| Temperature<br>K | Surface tension |        |
|------------------|-----------------|--------|
|                  | mN/m            | dyn/cm |
| 129.2            | 25.00           | 25.00  |
| 133.2            | 24.54           | 24.54  |
| 137.1            | 23.72           | 23.72  |
| 149.1            | 21.75           | 21.75  |
| 150.6            | 21.68           | 21.68  |
| 155.9            | 20.71           | 20.71  |
| 157.5            | 20.46           | 20.46  |
| 161.3            | 19.86           | 19.86  |
| 164.4            | 19.28           | 19.28  |
| 170.3            | 18.31           | 18.31  |
| 180.6            | 16.63           | 16.63  |

### 3.2.7 Thermal Conductivity of Ethane

Measurements of the thermal conductivity of ethane up to 5000 psia in the temperature interval between 278 and 444 K (40 and 340 °F) were made with a spherical conductivity cell [266]. The results were only in fair agreement with data of other investigators, which were obtained with entirely different types of instruments. The results were presented in tabular and graphical form. It appeared that the residual thermal conductivity is a single-valued function of weight throughout the range of conditions covered by this investigation. See also [137, 267, 268].

A coaxial cylinder method was used to measure the thermal conductivity of ethane in the pressure range from 10 up to 280 bar and in the temperature range from 308 up to 365 K [269].

The thermal conductivity of ethane in the critical region has been measured with a parallel-plate method as a function of temperature along 11 different isochores so as to obtain detailed information on the enhancement of the thermal conductivity in the critical region [270]. The experimental results appeared to be consistent with a theoretical equation that accounts for both the asymptotic and non-asymptotic critical behavior of the thermal conductivity of fluids in the critical region.

A set of equations for the thermal conductivity of ethane was based upon a body of experimental data that had been critically assessed for internal consistency and for agreement with theory in the zero-density limit and in the critical region [271]. The equations extended over the temperature range from 100 K to the critical temperature in the liquid phase and from 225 K to the critical temperature in the vapor phase. In the supercritical region the temperature range extended to 1000 K for pressures up to 1 MPa and to 625 K for pressures up to 70 MPa. The ascribed accuracy of the representation varied according to the thermodynamic state, from  $\pm 2\%$  for the thermal conductivity of the dilute gas near room temperature to  $\pm 5\%$  for the thermal conductivity at high pressures and temperatures. Thermal conductivity data generated by the equations at selected temperatures and pressures and along the saturation line were tabulated.

### 3.2.8 Critical Constants of Ethane

The critical-point properties of ethane are listed in Table 29.

**Table 29:** Critical-point properties of ethane and methane.

|         | $M$<br>g/mol | $T_c$<br>K          | $P_c$<br>MPa      | $\rho_c$<br>g/cm <sup>3</sup> | $V_c$<br>cm <sup>3</sup> /mol | $Z_c^a$ |
|---------|--------------|---------------------|-------------------|-------------------------------|-------------------------------|---------|
| Methane | 16.043       | $190.564 \pm 0.015$ | $4.599 \pm 0.003$ | $0.1627 \pm 0.0005$           | 98.60                         | 0.286   |
| Ethane  | 30.070       | $305.32 \pm 0.04$   | $4.872 \pm 0.01$  | $0.2066 \pm 0.003$            | 145.5                         | 0.279   |

<sup>a</sup>  $Z_c = P_c V_c / R T_c$ , where  $R = 8.31451 \text{ Pa m}^3 \text{ mol}^{-1} \text{ K}^{-1}$

Data source: [9]

Other sources used critical parameters of  $P_c = 4871.76 \text{ kPa}$  or  $48.0807 \text{ atm}$ ,  $T_c = 305.33 \text{ K}$ ,  $V_c = 0.14556 \text{ dm}^3/\text{mol}$ , and  $\rho_c = 6.870 \text{ mol/dm}^3$  [260].

### 3.2.9 Thermodynamic Properties of Ethane

The thermodynamic properties of ethane have been thoroughly investigated and are reported in several sources in the literature [257, 272].

### 3.2.9.1 Heat Capacity of Ethane

Experimental isobaric heat capacities of liquid ethane are listed in Table 30.

**Table 30:** Experimental isobaric heat capacities of liquid ethane.

| Temperature, K | Pressure, MPa | Isobaric heat capacity, J g <sup>-1</sup> K <sup>-1</sup> <sup>a</sup> |
|----------------|---------------|------------------------------------------------------------------------|
| 108.15         | 1.05          | 2.258                                                                  |
| 118.15         | 1.06          | 2.270                                                                  |
| 188.15         | 1.12          | 2.443                                                                  |
| 228.15         | 1.17          | 2.695                                                                  |
| 238.15         | 1.21          | 2.784                                                                  |
| 118.15         | 2.03          | 2.249                                                                  |
| 108.15         | 2.02          | 2.257                                                                  |
| 108.15         | 4.29          | 2.254                                                                  |

<sup>a</sup> Standard uncertainties  $u$  are  $u(T) = 0.5$  K for  $T < 220$  K,  $u(T) = 0.25$  K for  $T > 220$  K,  $u(p) = 35$  kPa, and combined expanded uncertainty  $Uc(c_p) = 0.02 c_p$  with a 95% level of confidence.

Data source: [194]

The heat capacities of gaseous ethane have been measured down to 93 K with a low pressure thermal conductivity apparatus [273]. A method of obtaining the heat capacities from the thermal conductivity data was described that does not require a knowledge of the accommodation coefficient  $\alpha$ . The heat capacity results for ethane indicated a potential barrier restricting internal rotation of the two molecule halves with a depth of 11.5 kJ/mol (2.75 kcal/mol).

The specific heats of saturated liquid ethane,  $C_\sigma$ , have been measured at 106 temperatures in the temperature range 93 to 301 K [274]. The specific heats at constant volume,  $C_v$ , have been measured at 19 densities ranging from 0.2 to 3.1 times the critical density, at temperatures between 91 and 330 K, with pressures up to 33 MPa, at 200 PVT states in all. The uncertainty of most of the measurements was estimated to be less than 2.0%. As the critical point was approached, the uncertainty rose to about 5.0%. The results for  $C_\sigma$  for the temperature range 93 to 301 K were represented with an analytical equation as follows:

$$C_\sigma = C_1 + C_2 T + \frac{C_3 T}{(T_c - T)^{0.6}} + \frac{C_4}{T} + \frac{C_5}{T^2}$$

**Table 31:** Constants for saturated heat capacity equation of liquid ethane.

| Constant | Value             |
|----------|-------------------|
| $C_1$    | 0.2264822683E+02  |
| $C_2$    | 0.8796160711E-01  |
| $C_3$    | 0.1090640627E+01  |
| $C_4$    | 0.5371201054E+04  |
| $C_5$    | -0.2123389640E+06 |

Data source: [274]

where  $T_c$  is the critical temperature, 305.33 K and values of the coefficients are given in Table 31. At 298 K the vapor pressure was 4.2086 MPa, the density was 10.426 mol/L, and the measured saturated heat capacity was 167.24 J mol<sup>-1</sup> K<sup>-1</sup>.

Additional data on the heat capacity of ethane are available from Wiebe et al. [275] and Witt and Kemp [276]. Isobaric enthalpy increment measurements were made on liquid ethane over the temperature range 146.0 to 256.2 K and pressure ranges 1.16 to 5.07 MPa using an electrically heated flow calorimeter [277].

### 3.2.9.2 Heat of Combustion of Ethane

The upper heat of combustion of gaseous ethane is 1560.69 ± 0.25 kJ/mol (373.01 ± 0.06 kcal/mol) [197].

### 3.2.9.3 Enthalpy of Vaporization of Liquid Ethane

The enthalpy of vaporization of ethane at the normal boiling point (184 K) is 14.703 kJ/mol (3.514 kcal/mol).

### 3.2.10 Dielectric Constant of Liquid Ethane

The dielectric constant of ethane in the saturated liquid and compressed fluid states was measured at temperatures between 95 and 323 K and at pressures ranging up to 390 bar [278]. The data were combined with accurate density data from several sources to produce the Clausius-Mossotti function over a wide range of temperature and density. An analytical expression of the Clausius-Mossotti function was given, and the consistency of the available density data was examined.

## 3.3 Flammability Limits of Ethane

The flammable limits of ethane in air with upward propagation are from 3.0 to 12.4 vol.-% C<sub>2</sub>H<sub>6</sub> in air. The autoignition temperature is 788 K (515 °C). Limits of flammability of ethane in other oxidizing atmospheres have been measured as well [279].

### 3.4 Fuel Mixtures with Ethane

Fuel mixtures of ethane with methane were already discussed in this chapter, Section 2.8.1 on methane.

The heat of combustion and the specific impulse of ethane can be increased by suspending metal particles in the liquid fuel. In order to prevent the metal particles from settling, the liquid fuel has to be gelled. It is difficult to find suitable gelling agents for cryogenic propellants.

Aluminized ethane and propane gels have been evaluated along with other gelled hydrocarbon fuels [280, 281]. The gellants included alkoxides and silica-based materials. Hexane, ethane, propane, and hydrogen were gelled and their rheological properties were determined: shear stress versus shear rate and their attendant viscosities. Gellant concentrations were varied from 0.75 to 3.05 mass-%. The metal-loaded dispersions exhibited pseudoplastic behavior similar to that observed for the neat gels. The ethane gel had a much thicker consistency than the propane gel, as is evident by the higher  $k$  value ( $0.47 \text{ Pa}\cdot\text{s}^{0.22}$  versus  $0.22 \text{ Pa}\cdot\text{s}^{0.22}$ ), where  $k$  is a measure of viscosity.

## 4 Propane

Propane,  $\text{C}_3\text{H}_8$ ,  $\text{H}_3\text{C}-\text{CH}_2-\text{CH}_3$ , dimethylmethane, CAS RN [74-98-6], is a colorless, odorless gas that is most frequently used as a compressed gas liquid at room temperature. The vapor pressure of propane at 298 K is 0.94844 MPa (9.36 atm = 137 psia). Because propane can be handled as a liquid at room temperature it would make it easier to handle as a rocket propellant than methane or ethane, which requires cryogenic handling apparatus. A common name for liquid propane is liquefied petroleum gas.

Propane can be separated from natural gas and gas released when crude oil is brought to the surface. Propane and propylene are formed during the cracking of crude oil to produce lighter (gasoline) fractions. The ideal work required for liquefaction of propane starting at 300 K and 101.3 kPa is 140.4 kJ/kg (60.4 BTU/lb).

### 4.1 Physical Properties of Propane

The free mini-REFPROP computer program, which can be downloaded from the National Institute of Standards and Technology (NIST) website [38], contains propane as an example. It can instantly create physical and thermochemical property tables and graphs for a wide range of temperatures. The thermophysical properties of propane are reported in Younglove and Ely [94]. The physical properties of propane are summarized in Table 32.

**Table 32:** Physical properties of propane.

| Property                                                       | SI units                                  | Other units                                                   | References |

#### 4.1.1 Freezing Point of Propane

The triple point properties of propane are listed in Table 33. Other sources reported a triple-point temperature of  $85.525 \pm 0.005$  K [282].

**Table 33:** Triple-point properties of propane.

|             |                                              |
|-------------|----------------------------------------------|
| $T_t$       | 85.47 K                                      |
| $P_t$       | $1.6850 \times 10^{-10}$ MPa                 |
| $\rho_{tL}$ | 16.636 mol/dm <sup>3</sup>                   |
| $\rho_{tV}$ | $2.3775 \times 10^{-10}$ mol/dm <sup>3</sup> |

Data source: [94]

#### 4.1.2 Boiling Point of Propane

The boiling point of propane is 231.0679 K (−42.08 °C) [283]. The density of liquid propane at boiling point is 13.1687 mol/L.

### 4.1.3 Vapor Pressure of Propane

The vapor pressure of propane is illustrated in Figure 23.

**Figure 23:** Vapor pressure of propane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology data.)

The vapor pressure of propane within the range 230.6 to 320.7 K (above the normal boiling point) can be calculated from the Antoine equation

$$\log P = A - B/(T + C) = 3.98292 - [819.296/(T - 24.417)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

The vapor pressure of propane within the range 166.02 to 231.41 K (below the normal boiling point) can be calculated from the Antoine equation

$$\log P = A - B/(T + C) = 4.01158 - [834.26/(T - 22.763)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. This equation gives a vapor pressure of 8.56 bar (124 psia) at 293 K (20 °C) and 9.73 bar (141 psia) at 298 K (25 °C). These two equations were used in constructing Figure 23.

### 4.1.4 Density of Propane

The density of liquid and vapor propane under saturation conditions as a function of temperature is illustrated in Figure 24.

**Figure 24:** Density of saturated propane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology data.)

#### 4.1.5 Viscosity of Propane

The viscosity of propane under saturation conditions as a function of temperature is illustrated in Figure 25.

The viscosity of propane was measured in the liquid and gas phases at pressures up to 34.5 MPa (5000 psia) in the temperature interval between 278 and 478 K (40 and

**Figure 25:** Viscosity of saturated propane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology data.)

400 °F) [284]. These measurements served to corroborate and extend the results reported in more extensive investigations carried out with entirely different types of instruments. For the most part, satisfactory agreement between several sets of investigations has been found. However, earlier measurements carried out with a rolling-ball viscometer indicated that the latter type of instrument is entirely unsuitable for measurements in the gas phase. Utilizing the current experimental data obtained for propane along with those that have been recorded in connection with the viscosity of ethane and *n*-butane, a comparison was made with the data reported by several investigators using various types of instruments.

Viscosity and thermal conductivity of gaseous and liquid propane have been measured and represented by empirical functions developed in previous work [285]. Tables of values were presented for the range 140–500 K and for pressures up to 50 MPa (500 atm). The viscosities were estimated to have uncertainties of about  $\pm 5\%$ . Dynamic viscosity of liquid propane is illustrated in Figure 26. The data in Figures 25 and 26 are essentially identical.

**Figure 26:** Viscosity of liquid propane along the saturation line. (Image created by Schmidt 2020 based on data from [285])

High-precision viscosity measurements on gaseous propane were performed in a quartz oscillating-disk viscometer with small gaps from room temperature up to about 625 K and for densities between 0.01 and 0.05 mol/L [286]. The experimental data were evaluated with a first-order expansion, in terms of density, for the viscosity. Reduced values of the second viscosity virial coefficients deduced from the zero-density and initial-density viscosity coefficients for propane and for higher *n*-alkanes were in close agreement with the theoretical representations. A new representation of the viscosity of propane within the limit of zero density was

provided using the new experimental data and some data sets from the literature. The universal correlation based on the extended principle of corresponding states extended over the temperature range 293 to 625 K with an uncertainty of  $\pm 0.5\%$  and deviated from earlier representations by about 1% at the upper temperature limit. The standard reference viscosity of propane gas at 298 K and 101 kPa is 8.1327  $\mu\text{Pa}\cdot\text{s}$ .

A different representation of the viscosity of propane included a zero-density correlation and an initial-density dependence correlation based on the kinetic theory of dilute gases [287]. The higher density contributions of the residual viscosity in the representation were formed by a combination of double polynomials in density and reciprocal temperature, and a free-volume term with a temperature-dependent close-packed density. The full surface correlation was based on a set of primary experimental data selected as a result of a critical assessment of the available information from 37 original viscosity studies, referring to 96 citations altogether. The validity of the representation extended from the triple point to 600 K and 100 MPa in accordance with the modified Benedict-Webb-Rubin equation of state. Tables of the viscosity according to the representative equations at selected temperatures and pressures and along the saturation line provided easy reference as well as a validation of computer codes. A re-evaluation of the viscosity data concerned the determination of the wire radius using an improved calibration [288].

An apparatus combining a vibrating-wire viscometer and a single-sinker densimeter was used to provide accurate  $\eta p p T$  data for four isotherms on ethane at 293, 307, and 423 K and five isotherms on propane at 273, 298, 366, 373, and 423 K [265]. The maximum pressure was chosen to be about 95% of the saturated vapor pressure for the subcritical isotherms and a maximum of 30 MPa for the supercritical isotherms. Near the critical region, allocation errors for temperature and pressure have a significant impact on the uncertainty of the experimental densities. The new viscosity data and earlier data that had also been re-evaluated were compared with the viscosity surface correlations by others for ethane and propane as well as with selected experimental data for the low-density region. These viscosity data can be used to improve the viscosity surface correlations available in the literature.

Another viscosity formulation for propane, using the reference equation of state for its thermodynamic properties by Lemmon, McLinden, and Wagner [289] and valid in the fluid region from the triple-point temperature to 650 K and pressures up to 100 MPa was based on a zero-density contribution and one for the critical enhancement, each based on experimental data [290]. The higher-density contributions were correlated as a function of the reciprocal reduced temperature  $\tau = T_c/T$  and of the reduced density  $\delta = \rho/\rho_c$  ( $T_c$  = critical temperature,  $\rho_c$  = critical density). The final formulation included 17 coefficients inferred by applying a linear optimization algorithm. Tables of viscosity data computed for the most recent formulation were given in an appendix for the single-phase region, for the vapor-liquid phase boundary, and for the near-critical region. See also [113].

#### 4.1.6 Surface Tension of Propane

The surface tension of propane along the saturation boundary under saturation pressure is illustrated in Figure 27.

**Figure 27:** Surface tension of propane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology RefProp data.)

#### 4.1.7 Thermal Conductivity of Propane

The thermal conductivity of propane under saturated liquid and vapor conditions is illustrated in Figure 28. The two curves for liquid and vapor propane meet at the critical point.

From RefProp, a calculation of the thermal conductivity of liquid propane at the saturation pressure at 295 K gives  $95.196 \text{ mW m}^{-1} \text{ K}^{-1}$  and the thermal conductivity of the saturated pressure gas phase above it is  $18.505 \text{ mW m}^{-1} \text{ K}^{-1}$ .

The thermal conductivity of propane was measured in both gas and liquid regions at temperatures and pressures above and below the critical point [291]. Five isotherms at 323, 341, 360, 379, and 413 K (122, 154, 189, 222, and 284 °F), and at pressures from 0.1 to 28.6 MPa (1 to 282 atm) were measured.

Thermal conductivity of gaseous and liquid propane have been measured and represented by empirical functions developed in previous work [286]. Tables of values were presented for the range 140–500 K and for pressures up to 50 MPa (500 atm). The thermal conductivity of liquid propane is illustrated in Figure 29. The data in Figures 28 and 29 are essentially identical.

The thermal conductivity of propane along seven isotherms from 110 to 300 K at pressures up to 70 MPa, with densities within the range 11–16.5 mol/L ( $0.484\text{--}0.726 \text{ g/cm}^3$ ) was measured and compared with literature data for liquid propane [137, 292].

**Figure 28:** Thermal conductivity of saturated liquid and gaseous propane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology RefProp data.)

**Figure 29:** Thermal conductivity of liquid propane along the saturation line. (Image created by Schmidt 2020 based on data from [285].)

A coaxial cylinder method was used to measure the thermal conductivity of propane in the pressure range from 1 to about 70 MPa and in the temperature range from room temperature to 578 K (305 °C), extending data coverage to the critical region [293].

Thermal conductivity of propane was measured over the temperature range 192–320 K, at pressures up to 70 MPa, and densities to 15 mol/L, using a transient line-source instrument [294]. The experimental results were presented in the form of

a correlation together with other available data in the range 110–580 K up to 70 MPa, including the anomalous critical region.

Experimental data on the thermal conductivity of gaseous propane, covering a temperature range of 110 to 700 K and a pressure range of 0.1 to 70 MPa, were used together with previously available data to develop an improved empirical equation for the thermal conductivity of gaseous and liquid propane [295]. The quality of the new data was such that the thermal conductivity correlation for propane was estimated to have an uncertainty of about  $\pm 5\%$  at a 95% confidence level, with the exception of points near the critical point, where the uncertainty of the correlation increased to  $\pm 10\%$ .

Additional experimental data on the thermal conductivity of propane allowed improved correlations to be developed. Previous correlations had been limited by a lack of thermal conductivity data for the vapor at temperatures below 300 K and liquid data near the critical point. In addition, significant discrepancies were noted in the thermal conductivity of high-temperature dilute gas. Measurements over the temperature range from the triple point at 85.5 to 600 K and the pressure range 0.1 to 70 MPa were estimated to have an uncertainty of 1% for measurements removed from the critical point and at pressures above 1 MPa, which increases to 3% in the critical region and 4% at low pressures ( $<1$  MPa) [296]. These experimental data were used together with previously available data to develop improved correlations for the thermal conductivity of propane.

Measurements of the thermal conductivity of propane over the temperature range from 370.83 to 381.00 K, and the pressure range 0.1 to 15 MPa were performed in a coaxial cylinder cell operating under steady-state conditions and were extended along eight quasi-isotherms to above the critical temperature [297]. The parameters of a background equation were determined from experimental data in order to analyze the critical enhancement of the thermal conductivity as a function of temperature and density. On the basis of the measurement of more than 500 experimental points, a phenomenological equation was provided to describe the thermal conductivity of propane, from the critical temperature 369.825 to 600 K and densities up to  $550 \text{ g/cm}^3$ . This equation can be generalized to calculate the supercritical behavior of the thermal conductivity for any fluid.

#### 4.1.8 Heat Transfer Coefficient of Liquid Propane

Heat transfer characteristics of propane were experimentally evaluated in heated tube tests [298–300]. Forced convection heat transfer coefficients were determined over the range of fluid conditions covering operating condition from 3.1 to 12.4 MPa (450 to 1800 psia), 116 to 394 K ( $-250$  to  $+250$  °F), and 15 to 45 m/s (50 to 150 ft/s), with wall temperatures from ambient to 922 K (1200 °F), and heat fluxes to  $1634 \text{ W/cm}^2$  ( $10 \text{ BTU in}^{-2} \text{ s}^{-1}$ ). Nucleate boiling and coking were also evaluated. Coking occurred over a wide temperature range. Coking rate was comparable with published data for RP-1. Propane purity affected the rate but not the threshold temperature of coking.

When testing a LOX/propane rocket engine, carbon deposition in the acoustic cavities was extensive to the point that acoustic damping capabilities could be lost. Burnout heat flux was found to be considerably higher than an extrapolation of available low heat flux data would have predicted. Operating with propane at subcritical pressures was unacceptable because of low burnout heat flux. The low wall temperature threshold determined for the coking of propane, combined with the incompatibility of commercial propane with copper, the material of choice for high pressure regeneratively cooled chambers because of its high thermal conductivity, may eliminate propane as a candidate propellant for certain applications. Otherwise, propane would offer a desirable combination of high combustion performance and high mass density.

A series of heat transfer tests with propane was conducted at pressures of 0.5–30 MPa, flow velocities of 2–106 m/s, and heat fluxes up to 66 MW/m<sup>2</sup> in stainless-steel and copper tubes, and the deposit formation rates for kerosene in tubes were measured [152]. Forced convective heat transfer correlations were obtained for liquid methane, liquid propane, and kerosene, up to extreme heat fluxes at which test tubes burnt out. The test results indicated that heat transfer coefficients of methane and propane decreased at high wall temperatures.

#### 4.1.9 Critical Constants of Propane

The critical constants of propane and butane are listed in Table 34. Other sources gave  $T_c = 369.80$  K,  $P_c = 42.3974$  bar,  $\rho_c = 4.96$  mol/L [69].

**Table 34:** Critical-point properties of propane and butane.

|         | $M$<br>g/mol | $T_c$<br>K   | $P_c$<br>MPa | $\rho_c$<br>g/cm <sup>3</sup> | $V_c$<br>cm <sup>3</sup> /mol | $Z_c^a$ |
|---------|--------------|--------------|--------------|-------------------------------|-------------------------------|---------|
| Propane | 44.097       | 369.83 ± 0.1 | 4.248 ± 0.01 | 0.220 ± 0.003                 | 200                           | 0.277   |
| Butane  | 58.123       | 425.12 ± 0.1 | 3.796 ± 0.01 | 0.228 ± 0.003                 | 255                           | 0.274   |

<sup>a</sup>  $Z_c = P_c V_c / R T_c$ , where  $R = 8.31451$  Pa m<sup>3</sup> mol<sup>-1</sup> K<sup>-1</sup>

Data source: [9]

#### 4.1.10 Thermodynamic Properties of Propane

An equation of state was developed for the thermodynamic properties of propane that was valid for temperatures from the triple-point temperature (85.525 K) to 650 K and for pressures up to 1000 MPa [289]. The formulation can be used for the calculation of all thermodynamic properties, including density, heat capacity, velocity of sound, energy, and saturation properties. Comparisons with available experimental data established the accuracy of calculated properties. The approximate uncertainties of properties calculated with the new equation are 0.01 to 0.03% in density below 350 K, 0.5% in

heat capacities, 0.03% in the velocity of sound between 260 and 420 K, and 0.02% in vapor pressure above 180 K. Deviations in the critical region were higher for all properties except for vapor pressure.

#### 4.1.10.1 Heat Capacity of Propane

Experimental isobaric heat capacities of liquid propane are listed in Table 35.

**Table 35:** Experimental isobaric heat capacities of liquid propane.

| Temperature, K | Pressure, MPa | Isobaric heat capacity, $\text{J g}^{-1} \text{K}^{-1}$ |
|----------------|---------------|---------------------------------------------------------|
| 108.15         | 1.16          | 1.927                                                   |
| 118.15         | 1.17          | 1.922                                                   |
| 128.15         | 1.18          | 1.934                                                   |
| 143.15         | 1.13          | 1.960                                                   |
| 153.15         | 1.19          | 1.987                                                   |
| 163.15         | 1.17          | 1.995                                                   |

| 153.15         | 5.20          | 2.011                                                   |
| 163.15         | 5.21          | 2.026                                                   |
| 188.15         | 5.22          | 2.066                                                   |
| 228.15         | 5.22          | 2.225                                                   |
| 238.15         | 5.22          | 2.282                                                   |
| 248.15         | 5.19          | 2.301                                                   |
| 258.15         | 5.22          | 2.353                                                   |
| 108.15         | 5.33          | 1.923                                                   |
| 118.15         | 5.43          | 1.938                                                   |
| 128.15         | 5.43          | 1.940                                                   |

Standard uncertainties  $u$  are  $u(T) = 0.5 \text{ K}$  for  $T < 220 \text{ K}$ ,  $u(T) = 0.25 \text{ K}$  for  $T > 220 \text{ K}$ ,  $u(p) = 35 \text{ kPa}$ , and combined expanded uncertainty  $Uc(c_p) = 0.02 c_p$  with a 95% level of confidence.

Data source: [194]

The heat capacity of propane is illustrated in Figure 30. The two curves for liquid and gaseous propane run very close to each other.

**Figure 30:** Heat capacity  $c_p$  of liquid and vapor propane at saturation point. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

Experimental specific heats for saturated liquid propane along the coexistence path have been determined from the triple-point temperature (85 K) to 289 K (Figure 31) [283]. Specific heats for the compressed liquid at a constant molar volume have been determined along isochors at nine different densities ranging from near the triple-point liquid density to about twice the critical-point density (at pressures up to 300 bar). Comparisons with previous experimental and/or derived data showed agreement within combined uncertainties of about 3%.

Molar heat capacities at constant volume ( $C_V$ ) from 85 to 345 K with pressures to 35 MPa were measured with an adiabatic calorimeter for pure propane [301]. The high purity of the samples was verified by chemical analysis. Measurements were conducted on liquid propane in equilibrium with its vapor and on compressed liquid samples along isochors. Heat capacity results were reported for two-phase ( $C_{V(2)}$ ), saturated liquid ( $C_{\sigma}$ ), and single-phase ( $C_V$ ) isochors. Vapor pressure data were based on measurements of  $C_{V(2)}$  along a two-phase isochore. Measurements were also made to determine the triple-point temperature of  $85.525 \pm 0.005$  K and heat of fusion of  $3508 \pm 20$  J/mol for propane near its triple point. The principal sources of uncertainty in  $C_V$  were the temperature rise measurement and the change-of-volume work adjustment.

**Figure 31:** Specific heat of saturated liquid propane. (Reproduced and modified from [69].)

#### 4.1.10.2 Heat of Combustion of Propane

The upper heat of combustion of propane gas is  $2219.17 \pm 0.46$  kJ/mol ( $530.39 \pm 0.11$  kcal/mol) [197].

#### 4.1.10.3 Enthalpy of Formation of Propane

The standard enthalpy of formation of liquid propane at 298 K is  $-119.8 \pm 0.59$  kJ/mol ( $-28.6$  kcal/mol). The standard enthalpy of formation of propane vapor at 298 K is  $-104.7 \pm 0.50$  kJ/mol ( $-25.0$  kcal/mol).

#### 4.1.10.4 Enthalpy of Fusion of Propane

The heat of fusion of propane is  $3508 \pm 20$  J/mol ( $0.84$  kcal/mol) [301].

#### 4.1.10.5 Enthalpy of Vaporization of Liquid Propane

The enthalpy of vaporization of propane at the normal boiling point at 231.1 K and 101 kPa is 19.04 kJ/mol (4.55 kcal/mol). The dependence of the enthalpy of vaporization on temperature (and pressure) under saturation conditions is illustrated in Figure 32. The enthalpy of vaporization approaches zero as the temperature increases to near the critical temperature.

**Figure 32:** Enthalpy of vaporization of propane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

## 4.2 Chemical Properties of Propane

### 4.2.1 Thermal Decomposition and Coke Deposition of Propane

A high-pressure fuel coking test apparatus was used to evaluate thermal decomposition (coking) limits and carbon deposition rates in heated copper tubes for commercial-grade propane [302]. Tests were conducted using JP-7 and chemically pure propane as being representative of more refined cuts of the baseline fuels. A parametric evaluation of fuel thermal stability was performed at pressures of 136 to 340 atm, bulk fuel velocities within the range 6–30 m/s and tube wall temperatures within the range 422–811 K. The effect of the inside wall material on deposit formation was evaluated in selected tests using nickel-plated tubes. The carbon deposition rates for the propane fuels were generally higher than those obtained for either of the kerosene fuels at any given wall temperature. Plating the inside wall of the tubes with nickel was found to significantly reduce carbon deposition rates for RP-1 fuel.

The heat transfer characteristics of propane at subcritical and supercritical pressure were experimentally evaluated using electrically heated Monel K-500 tubes [303, 304]. A design correlation for supercritical heat transfer coefficient was established using the same approach previously applied to supercritical oxygen. Flow oscillations were observed and the onset of these oscillations at supercritical pressures correlated with wall-to-bulk temperature ratio and velocity. The critical heat flux measured at subcritical pressure correlated with the liquid velocity and subcooling. Long-duration tests under fixed heat flux conditions were conducted to evaluate coking on the coolant side tube wall. Coking rates comparable with those with RP-1 were observed.

#### 4.2.2 Radiolysis of Propane

Methane and propane radiolysis reactions go by different routes. A comparative study of variations of  $G(H_2)$  with respect to temperature at very small conversions in a hydrocarbon in which abstraction is believed to predominate at room temperature ( $C_3H_8$ ) and in  $CH_4$  might provide more definitive insight into the question of the apparent inertness of methane to H atom attack [21].

Propane or methane, ethane, or ethene were irradiated to study radiation effects on stored liquid propellants on spacecraft with auxiliary RTG or nuclear power sources [23, 24]. Radiation experiments with propane at the higher dose rate were done in 1100F aluminum vessels to see if there were any obvious effects attributable to container materials. Samples of the gas above liquid propane at 195 K ( $-78^\circ\text{C}$ ) were analyzed by mass spectrometry (MS). The results showed the major gaseous products to be unsaturated  $C_2$  compounds, acetylene and ethene. Methane was also always present in significant quantities. The surprising result in these analyses was the general absence of hydrogen. From the amount of unsaturated compounds present there should have been easily discernible amounts of hydrogen. One might suspect that the hydrogen reacted with the titanium vessel in which the irradiation was performed. Such a reaction is less likely with an aluminum vessel, however, but there was no difference. Low-dose-rate experiments were also conducted with liquid propane in titanium vessels for a period of almost 4 months at an average dose rate of  $4.80 \times 10^3$  rad/h.

#### 4.3 Materials Compatibility with Propane

Materials compatibility of hydrocarbon fuels (propane, methane, Mil-Spec RP-1, and *n*-dodecane) in contact with copper-based combustion chamber liner materials (OFHC, NASA-Z, and ZrCu coppers) was tested using two different methods [216]. Static tests, in which copper coupons were exposed to fuel for long durations at constant temperature and pressure, provided compatibility data in a precisely controlled environment. Dynamic tests, using the Aerojet Carbothermal Test Facility, provided fuel and copper compatibility data under realistic booster engine service conditions. Tests were conducted using very pure grades of each fuel and fuels to which a contaminant, e.g., ethene or methyl mercaptan, was added to define the role played by fuel impurities. It was found that each of the copper materials exhibited similar compatibility behavior. However, there were significant differences among the various hydrocarbon fuels tested. In propane, no carbon deposits were formed up to  $T_{\text{wall}} = 736$  K ( $865^\circ\text{F}$ ) and copper corrosion was observed in all tests with sulfur contents down to 1 ppm. Copper(I) sulfide is the corrosion product.

## 4.4 Safety Properties of Propane

### 4.4.1 Toxicity of Propane

Propane, like most lower hydrocarbons, is mostly acting as an asphyxiant and narcotic when inhaled at concentrations of several percent by volume in air. The NIOSH REL is 1000 ppm (1800 mg/m<sup>3</sup>) and the OSHA TWA is also 1000 ppm (1800 mg/m<sup>3</sup>). It has been reported that brief inhalation exposures up to 10000 ppm propane in air caused no symptoms in humans.

Propane is a simple asphyxiant and does not present an Immediately Dangerous to Life and Health (IDLH) hazard at concentrations below its lower explosive limit (LEL). The original IDLH was based on the LEL of 21000 ppm rounded down to 20000 ppm, but it was later lowered to 2100 ppm which is 10% of the LEL.

Commercially sold propane is scented with an odorant for safety reasons to make leaks more readily detectable before they reach the flammable range.

### 4.4.2 Flammable Range of Propane

The flammable range of propane is from 2.1 to 9.5 vol.-% in air. The lower temperature limit of flammability is at 171 K (−102 °C). The autoignition temperature in air is 723 K (450 °C).

### 4.4.3 Detonation of Air/Propane Mixtures

During a study of the venting of a fast flame (100–800 m/s) in a round ignition pipe (140 mm I.D.) into a semispherical vessel containing a mixture of the same composition and initial pressure, the flame jet emerging from the pipe interacted with the remains of an unburned starting ring vortex set into motion by the accelerating flame front, and the subsequent intense combustion lead to the initiation of an unconfined detonation inside the vessel [235]. A parametric investigation of this phenomenon in nitrogen-diluted (29.4–68.4 vol.-%) stoichiometric mixtures of oxygen/propane has been carried out for a range of exit orifice diameters (50, 101, and 140 mm) under initial pressure of 0.4 and 1 atm. A small number of atmospheric pressure experiments have also been conducted with nitrogen-diluted (33.3–57.1 vol.-%) stoichiometric oxygen/methane mixtures. A criterion, based on the notion of a critical Damköhler number and minimum energy release requirement, has been suggested for the initiation of unconfined detonation by a venting jet flame. All experimental results for a given initial pressure and fuel may be combined into a single curve, separating conditions leading to detonation from those that do not. The critical orifice diameter below which a transition to unconfined detonation does not occur was reduced for a venting fast flame by comparison with a steady detonation wave.

#### 4.5 Gelled Propane

The performance of propane and other hydrocarbons as fuels in bipropellant rocket engines can be increased by the addition of metal powders with high heats of combustion and high densities. In order to prevent the solid particles from settling during storage, the liquid needs to be gelled. Several gelling agents have been proposed for propane [305, 306]. The bipropellant system may be, but need not be, hypergolic (depending on the type of oxidizer used).

### 5 Butane and Pentane

Butane or pentane have not yet been used as fuels in rocket propellants. A hydrogen peroxide/butane dual mode bipropellant thruster named Halcyon has been proposed by Tesseract/Benchmark Space Systems. Traces of butane or pentane may be found in other hydrocarbons used as rocket fuels. Information on these hydrocarbons can be obtained from other literature sources.

#### 5.1 Physical Properties of Butane and Pentane

Thermophysical properties of *n*-butane are summarized in [94, 307, 308]. The heats of combustion and enthalpies of formation of ten gaseous C<sub>4</sub> hydrocarbons were measured in a calorimeter at ambient pressure [309]. The enthalpy of formation of *n*-butane vapor is  $-127.1 \pm 0.7$  kJ/mol ( $-30.37 \pm 0.16$  kcal/mol).

### Higher (C>5) Aliphatic Hydrocarbons

#### 6 Hexane

Hexanes, C<sub>6</sub>H<sub>14</sub>, and heptanes, C<sub>7</sub>H<sub>16</sub>, are typical constituents of gasoline, but are not used as rocket fuels in the pure state. Hexane has five isomers. *n*-Hexane, CAS RN 110-54-3, is often used as a model compound to determine the physical properties of hydrocarbons in gasoline in a more reproducible manner. *n*-Hexane is used as a constituent in gasoline surrogate mixtures. Because hexane is more readily available in pure form than other hydrocarbons, it is often used for thermal decomposition studies that are also useful for evaluating the thermal decomposition of other hydrocarbon rocket fuels.

## 6.1 Physical Properties of Hexane

The physical properties of *n*-hexane are listed in Table 36.

**Table 36:** Physical properties of *n*-hexane.

| Property                                               | SI units                                   | Other units                                                                   | References    |

<sup>a</sup> NBP = normal-boiling point

The vapor pressure of *n*-hexane within the range 286.18–342.69 K can be calculated using an Antoine equation

$$\log P = 4.00266 - [1171.53 / (T - 48.784)]$$

where *P* is the pressure in bar and *T* is the temperature in kelvin. This vapor pressure function for temperatures below the NBP is illustrated in Figure 33.

Reference equations for the thermal conductivity of *n*-hexane were based in part upon a body of experimental data that had been critically assessed for internal consistency and for agreement with theory whenever possible [313]. In the case of the thermal conductivity of dilute gas, a theoretically based correlation was adopted in order to extend the temperature range of the experimental data. In the critical region, the experimentally observed enhancement of the thermal conductivity was well rep-

**Figure 33:** Vapor pressure of *n*-hexane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology data.)

resented by theoretically based equations containing just one adjustable parameter. The correlations were applicable for the temperature range from the triple point to 600 K and pressures up to 500 MPa.

## 7 Heptane

Heptanes,  $C_7H_{16}$ , are typical constituents of gasoline. Heptane has 12 isomers. *n*-Heptane, CAS RN [142-82-5], is a natural constituent of many gasolines and jet engine fuels and is often used as a model compound to determine the physical properties of hydrocarbons in gasoline in a more reproducible manner. *n*-Heptane is used as a constituent in gasoline surrogate mixtures. Heptane may be present as the low boiling fraction of kerosenes used as jet fuels or rocket propellants. Because heptane is more readily available in pure form than other hydrocarbons, it is often used for thermal decomposition studies that are also useful for evaluating the thermal decomposition of other hydrocarbon rocket fuels.

### 7.1 Physical Properties of Heptane

The physical properties of *n*-heptane are listed in Table 37. The boiling points of hydrocarbons are usually divided into a lower range for gasolines and an upper range for kerosenes. The boiling points of heptanes are more in the boiling range of gasolines than that of kerosenes.

**Table 37:** Physical properties of *n*-heptane.

| Property                                                | SI units                                   | Other units                                                                   | References |

The vapor pressure of *n*-heptane in the range 299.07–372.43 K can be calculated using an Antoine equation

$$\log P = 4.02832 - [1268.636 / (T - 56.199)]$$

where *P* is the pressure in bar and *T* is the temperature in kelvin. The vapor pressure of *n*-heptane below its normal boiling point at 101 kPa is illustrated in Figure 34.

The viscosities of *n*-heptane and *n*-octane and their binary mixtures were measured as part of calibrating a two-capillary viscometer [315].

Equations for the thermal conductivity of *n*-heptane were based in part upon a body of experimental data that had been critically assessed for internal consistency and for agreement with theory whenever possible [316]. In the case of the thermal conductivity of dilute gas, a theoretically based correlation was adopted in order to extend the temperature range of the experimental data. In the critical region, the experimentally observed enhancement of the thermal conductivity was well represented by theoretically based equations containing just one adjustable parameter.

**Figure 34:** Vapor pressure of *n*-heptane. (Image created by Schmidt 2020 based on National Institute of Standards and Technology data.)

The correlations were applicable for the temperature range from the triple point to 600 K and pressures up to 250 MPa.

*n*-Heptane is often used as a well-defined model compound for mixtures of hydrocarbons. Additional information on heat transfer to *n*-heptane is published in Greenfield [317] and Seader and Wagner [318].

The rate of evaporation of *n*-heptane droplets and other fuels in rocket engines determines the required characteristic length of rocket combustion chambers [319, 320].

## 7.2 Chemical Properties of Heptane

Pure *n*-heptane is not used as a rocket propellant, but it is often used as a well-defined model compound for mixtures of hydrocarbons.

### 7.2.1 Thermal Decomposition of *n*-Heptane

The thermal decomposition of *n*-heptane was studied because it is often a constituent of surrogate fuel mixtures with controlled composition or it is part of the light boiler fraction in other hydrocarbon mixtures obtained by the refining of petroleum.

### 7.2.2 Pyrolysis of *n*-Heptane

The pyrolysis of both saturated and unsaturated *n*-heptane was evaluated via shock tube over a pressure range of 25–50 atm and a temperature range of 1000–1350 K, with reaction times ranging from 1 to 3 ms [321]. Pyrolysis products consisted of several

species that included acetylene, ethane, ethene, propene, allene, propyne, 1-butene, 1-pentene, and 1-hexene owing to the thermal decomposition of *n*-heptane. It was observed that there was no pressure dependence for the decomposition of *n*-heptane and formation of acetylene at reflected shock pressures of 25 and 50 atm. This was probably because the reacting species were at the high-pressure limit.

Single pulse shock-tube oxidation and pyrolysis experiments with *n*-heptane were conducted at a nominal pressure of 3.95 atm over a temperature range of 900–1500 K examining how ignition delay may be influenced by the interactive chemistry of alkanes and their pyrolytic and oxidative decomposition products [322]. *n*-heptane pyrolysis led to the formation of methane, ethene, acetylene, and propylene. It was found that heptane, ethene, heptane-ethene, and heptane-ethene-methane mixtures had similar CO<sub>2</sub> formation temperatures. This suggested that the primary reasons for the difference in ignition delay of the individual constituents and their mixtures are the reactions of the parent fuel leading to formation of the smaller molecules and the thermochemistry of the system.

A study of the kinetics and product distribution during the cracking of heptane in the presence of steam was performed in a flow reactor under atmospheric pressure within a temperature range of 953–1033 K (680–760 °C), with a mass ratio of steam to heptane of 3:1 [323]. The overall decomposition of heptane was represented by a first-order reaction with activation energy of 249.1 kJ/mol and a frequency factor of  $3.13 \times 10^{13} \text{ s}^{-1}$ . The reaction products were analyzed using GC, the main product being ethene. A molecular reaction scheme, which consisted of a primary reaction and 24 secondary reactions between primary products, was used for modelling the experimental product yields.

*n*-Heptane is a key straight chain paraffin in the fossil-fuel industry. Pyrolysis of *n*-heptane at a high temperature was investigated by a series of ReaxFF-based reactive molecular dynamic simulations [324]. The pyrolysis intermediate reactions, important product/intermediate distributions, and corresponding kinetics behaviors were systematically analyzed at an atomistic level. The results indicated that the entire pyrolysis process is radical-dominated. The unimolecular dissociation was the main pathway of *n*-heptane decomposition. Initiation of the decomposition was mainly through C–C bond fission. Central C–C bonds would dissociate prior to the terminal ones. The apparent activation energy extracted from these computer simulations was 180–226 kJ/mol (43–54 kcal/mol) in the temperature range 2400–3000 K, which was reasonably consistent with the experimental results. Results of the pyrolysis of heptane can then be compared with the thermal decomposition of higher alkanes, such as *n*-dodecane found in RP-1 or RP-2.

## 8 Octane

Octanes,  $C_8H_{18}$ , are typical constituents of gasoline. Octane has 20 isomers. *n*-Octane, CAS RN [111-65-9], is often used as a model compound to determine the physical properties of hydrocarbons in gasoline in a more reproducible manner. *n*-Octane is used as a constituent in gasoline surrogate mixtures. *Iso*-octane is used to measure the tendency of internal combustion engines toward “knocking,” premature ignition by adiabatic compression before the spark plug is energized. The tendency of gasoline to cause knocking in a reciprocating compression combustion engine is expressed by the Octane Number.

### 8.1 Physical Properties of *n*-Octane

The physical properties of *n*-octane are listed in Table 38.

**Table 38:** Physical properties of *n*-octane.

| Property                                         | SI units                                   | Other units                                                                          | References |

| Critical pressure                                | $24.9 \pm 0.1 \text{ bar}$                 | $24.6 \pm 0.1 \text{ atm}$                                                           | [45]       |
| Critical density                                 | $2.034 \pm 0.007 \text{ mol/L}$            | $0.232 \text{ g/cm}^3$                                                               | [45]       |

The vapor pressure of *n*-octane in the range 326.08–399.72 K can be calculated using an Antoine equation

$$\log P = 4.04867 - [1355.126 / (T - 63.633)]$$

where  $P$  is the pressure in bar and  $T$  is the temperature in kelvin.

Polynomial equation correlations for the thermal conductivity of the pure fluids *n*-octane, *n*-nonane, and *n*-decane that are valid over a wide range of fluid states, from dilute gas to dense liquid, including an enhancement in the critical region were derived from literature data for octane and two other hydrocarbons [325]. The correlations represented the thermal conductivity to within the uncertainty of the best experimental data and will be useful for researchers working on thermal conductivity models for other hydrocarbon mixtures.

The thermal conductivity of liquid *n*-octane, a pure hydrocarbon often used as a model substance in heat transfer studies, is  $0.14528 \text{ W m}^{-1} \text{ K}^{-1} = 3.47 \times 10^{-4} \text{ cal cm}^{-1} \text{ }^{\circ}\text{C}^{-1} \text{ s}^{-1}$  [310].

## 9 Decane

Decane,  $\text{C}_{10}\text{H}_{22}$ , CAS RN [124-18-5], is often used as a model compound of uniform chemical composition for simulating mixtures of hydrocarbons in kerosenes. For this reason it is important to have a complete set of physical properties for *n*-decane and some of its isomers.

### 9.1 Physical Properties of Decane

The enthalpy of vaporization of *n*-decane at 298 K is  $51.42 \pm 0.26 \text{ kJ/mol}$  [326]. The heat of sublimation of *n*-decane at 298 K is  $80.3 \text{ kJ/mol}$ .

#### 9.1.1 Thermal Conductivity of Decane

Polynomial equation correlations for the thermal conductivity of the pure fluids *n*-octane, *n*-nonane, and *n*-decane that are valid over a wide range of fluid states, from dilute gas to dense liquid, including an enhancement in the critical region, were derived from literature data for decane and two other hydrocarbons [325]. The correlations represented the thermal conductivity to within the uncertainty of the best experimental data and will be useful for researchers working on thermal conductivity models for other hydrocarbon mixtures. A sample point at 300 K and 10 MPa is for a fluid that has a thermal conductivity of  $132.80 \text{ mW m}^{-1} \text{ K}^{-1}$ , a viscosity of  $926.37 \text{ } \mu\text{Pa s}$ , and a density of  $5.1504 \text{ mol/L}$ .

### 9.1.2 Heat Transfer Properties of Decane

Turbulent heat transfer of hydrocarbon fuels at supercritical pressure plays a crucial role in the regenerative cooling of aerospace propulsion systems. Flow dynamics in transient heat transfer of *n*-decane at a supercritical pressure of 5 MPa were numerically investigated, focusing on the effects of a number of key influential parameters, including the surface heat flux, surface heating rate, cooling tube length, and inlet flow velocity, on the transient responding behaviors [327]. The results indicated that the transient responding process is dictated by two fundamental mechanisms: the initial thermoacoustic oscillation, which is caused by strong fluid thermal expansion, and the subsequent transient convection. The thermoacoustic oscillating magnitude increased as the surface heat flux, surface heating rate and cooling tube length were increased, but it decreased as the inlet flow velocity was increased. The surface heating rate and cooling tube length exerted strong influences on the oscillating frequency of the thermoacoustic wave. The cooling tube length and inlet flow velocity significantly affected the second-stage transient convective process and thus the total transient responding time, which both increased as the cooling tube length was increased and/or the inlet flow velocity was decreased. The results are helpful for a fundamental understanding of the transient heat transfer mechanisms relevant to regenerative rocket engine cooling processes.

Supercritical pressure hydrocarbon fuels have shown deteriorated heat transfer rates and instabilities for some flow conditions. The flow and heat transfer instabilities in supercritical pressure *n*-decane were investigated experimentally with pressures of 2.5 and 3.0 MPa and inlet temperatures of 293–498 K (16–225 °C) [328]. The heat flux was slowly increased to observe the flow at different stages, as well as to obtain the boundary lines for a stability map. Seven stages were observed with different stability features. The transition to turbulence was found to be the main reason for the instability for stage b with slightly irregular oscillations, whereas dramatic variations of the thermal properties caused Helmholtz oscillations with regular frequencies and large amplitudes. The heat transfer deterioration, in conjunction with an instability with buoyancy owing to the density variation, was found to be the reason. Higher pressures, inlet mass flow rates or fluid temperatures or downward flow weakened the instabilities; thus, these remedies should be used in engineering designs to reduce the heat transfer deterioration and instability. The stability map provided further support for the non-linear dynamic theory explaining the oscillations.

## 9.2 Chemical Properties of Decane

### 9.2.1 Thermal Decomposition of Decane

The flow and heat-transfer behavior of thermal cracking *n*-decane was investigated experimentally and numerically [329]. An electrically heated vertical tube (inner diameter 2 mm) was used to study thermal cracking of supercritical pressure *n*-decane at various pressures, temperatures, and resident times. The results showed that the second-order reactions increased the formation rates of the light products (especially CH<sub>4</sub> and C<sub>2</sub>H<sub>4</sub>) for conversions greater than 13%, whereas the heavy product (C<sub>5</sub>–C<sub>9</sub>) formation rates were decreased. A global reaction model was given for *n*-decane conversions less than 13%, including 18 main product species. A computational fluid dynamics (CFD) model was developed using the real thermal properties and coupled with fuel flow, heat transfer, and wall thermal conduction. Three turbulence models were tried out and then compared with the experimental results. The predicted fuel and wall temperatures were in good agreement with experimental data. The results also showed that *n*-decane continues to crack with almost half of the *n*-decane conversion in the connection pipe. Thus, the thermal cracking in the connection pipe should be more carefully analyzed in cracking models.

The pyrolysis mechanism of *n*-decane as a component of some rocket fuels was studied at 773–943 K in a flow reactor under pressures of 3, 4, and 5 MPa [330]. GC/MS was used to analyze the pyrolysis products, which were mainly alkanes from C<sub>1</sub>–C<sub>9</sub> and alkenes from C<sub>2</sub>–C<sub>9</sub>. A kinetic model containing 164 species and 842 reactions was developed and validated by experimental results including the distributions of products and the chemical heat sink of fuel. The decomposition pathways of *n*-decane were illustrated through reaction flux analysis. It was concluded that the C<sub>4</sub>–C<sub>9</sub> alkanes are mainly generated by the recombinations of alkyls, whereas the small alkanes (C<sub>1</sub>–C<sub>3</sub>) are formed by H-abstraction reactions by C<sub>1</sub>–C<sub>3</sub> alkyl radicals. The applicability of previous models to supercritical pressure and high fuel concentration conditions was criticized. In contrast, the performance of the new model in reproducing the experimental data was reasonably good.

The supercritical pyrolysis and endothermicity capacity of *n*-decane were studied under different pressures [331]. Experimental results indicated that the main gaseous products are small molecular hydrocarbons (methane, ethane, ethene). Ethene and propene were the most abundant components under this set of experimental conditions. It was noticed that the influence of pressure on the production of ethene is greater than that of any others. The increase in pressure increased the conversion of fuel to enhance its endothermicity, but the increase in pressure also decreased the alkene/alkane ratio, which has negative effect on the improvement of the chemical heat sink capacity of the fuel. The influence of pressure on the endothermicity of *n*-decane is not a simple effect of promotion or inhibition, but differs within different temperature ranges.

A study of the global pyrolytic reaction mechanism of *n*-decane for problems with mild endothermic pyrolysis at supercritical pressures was based on the fact that the high-molecular-weight alkane or alkene components in a thermally decomposed *n*-decane mixture possess similar thermophysical properties [332]. They can thus be grouped together and represented by a single light species with similar properties. Numerical tests indicated that a reduced 12-species reaction mechanism for mild cracking of *n*-decane represents a reasonable choice in terms of model accuracy and efficiency. The reduced pyrolytic reaction mechanism was employed to study the effect of mild thermal decomposition of *n*-decane on turbulent convective heat transfer at supercritical pressures. The wall heat flux into the coolant can thus be increased significantly at high fluid temperatures, due mainly to heat absorption resulting from endothermic pyrolytic reactions.

The effect of pyrolysis and coke deposition of *n*-decane on heat-transfer performance was examined in a series of experiments at pressures of 1, 2.5, and 4 MPa in a resistance-heated tube to simulate conditions encountered in regenerative cooling engines with a length range of 30–100 cm [333]. The bulk inlet and outlet temperatures of fuel were held constant at 753 K (480 °C) and 803–1053 K (530–780 °C) respectively in the test section. The heat transfer coefficients were dependent on both pressure and heat flux, and there was a critical heat flux at about 0.4–0.5 MW/m<sup>2</sup> for sub- and super-critical pressures. Relatively low pressure during pyrolysis had great advantages under the condition of relatively high heat flux because of the higher heat transfer coefficients and reduced coking.

The pyrolysis of helium-seeded *n*-decane as a surrogate of the *n*-alkane fraction of JP-8 was studied over a temperature range of 1100–1600 K at a pressure of 80 kPa (600 mm Hg) [334]. The nascent products were identified *in situ* in a supersonic molecular beam via single photon vacuum ultraviolet photoionization coupled with a mass spectroscopic analysis of the ions in a reflectron time-of-flight mass spectrometer. The initial reaction products formed in the decomposition of *n*-decane, including radicals and thermally labile closed-shell species, effectively exclude mass growth processes. Eighteen different products were identified: molecular hydrogen (H<sub>2</sub>), C<sub>2</sub> to C<sub>7</sub> 1-alkenes (ethene [C<sub>2</sub>H<sub>4</sub>] to 1-heptene [C<sub>7</sub>H<sub>14</sub>]), C<sub>1</sub>–C<sub>3</sub> radicals (methyl [CH<sub>3</sub>], vinyl [C<sub>2</sub>H<sub>3</sub>], ethyl [C<sub>2</sub>H<sub>5</sub>], propargyl [C<sub>3</sub>H<sub>3</sub>], allyl [C<sub>3</sub>H<sub>5</sub>]), small C<sub>1</sub>–C<sub>3</sub> hydrocarbons (methane [CH<sub>4</sub>], acetylene [C<sub>2</sub>H<sub>2</sub>], allene [C<sub>3</sub>H<sub>4</sub>], methylacetylene [C<sub>3</sub>H<sub>4</sub>]), along with higher-order reaction products (1,3-butadiene [C<sub>4</sub>H<sub>6</sub>], 2-butene [C<sub>4</sub>H<sub>8</sub>]). On the basis of electronic structure calculations, *n*-decane decomposes initially by C–C bond cleavage (excluding the terminal C–C bonds) producing a mixture of alkyl radicals from ethyl to octyl. These alkyl radicals are unstable under experimental conditions and rapidly dissociate by C–C bond β-scission to split ethene (C<sub>2</sub>H<sub>4</sub>) plus a 1-alkyl radical with the number of carbon atoms reduced by two and 1,4-, 1,5-, 1,6-, or 1,7-H shifts followed by C–C β-scission producing alkenes from propene to 1-octene in combination with smaller 1-alkyl radicals. The higher alkenes become increasingly

unstable with rising temperature. When the C—C  $\beta$ -scission continues all the way to the propyl radical ( $\text{C}_3\text{H}_7$ ), it dissociates producing methyl ( $\text{CH}_3$ ) plus ethene ( $\text{C}_2\text{H}_4$ ). At higher temperatures, hydrogen atoms can abstract hydrogen from  $\text{C}_{10}\text{H}_{22}$  to yield *n*-decyl radicals, whereas methyl ( $\text{CH}_3$ ) can also abstract hydrogen or recombine with hydrogen to form methane. These *n*-decyl radicals can decompose via C—C-bond  $\beta$ -scission to  $\text{C}_3$  to  $\text{C}_9$  alkenes.

A three-dimensional (3D) model was developed for numerically investigating the flow and heat transfer of pyrolytically reacted *n*-decane with pyrolytic coking in the engine cooling tube under supercritical pressure [335]. The one-step global pyrolytic reaction mechanism and the kinetic coking model were incorporated into the numerical model to simulate the pyrolysis and pyrolytic coking process of *n*-decane. The numerical method was validated based on the good agreement between the current predictions and the experimental data. Numerical studies of the characteristics of pyrolysis and surface coking rate at the start time under various outer wall heat fluxes ranging from 1.2 to 1.8 MW/m<sup>2</sup> have been conducted under 5 MPa pressure. Results revealed that heat flux has a significant effect on the pyrolytic reaction and the distribution of the pyrolytic coking rate. In order to better understand the complicated unsteady physicochemical process, further investigations on coupling relationships between the turbulent flow, heat transfer, pyrolysis, and pyrolytic coking in 20 min under a high heat flux of 1.8 MW/m<sup>2</sup> have been performed. It was found that surface coking deteriorated the cooling ability of *n*-decane. The mechanisms of these physicochemical phenomena were analyzed in detail, which will be very helpful in the design of regenerative cooling channels.

A molecular kinetic model was developed to describe the thermal cracking of *n*-decane at supercritical pressures [336]. The apparent kinetic parameters at different pressures were optimized. Following model validation, the role of pressure on the chemical heat absorption rate during *n*-decane pyrolysis was investigated using a one-dimensional plug flow model. It was found that the heat absorption rate first increased and then slightly decreased as the temperature increased at all pressures. The highest chemical heat absorption rate was located at a conversion of 41.81, 53.34, and 59.40% at 3, 4, and 5 MPa respectively. In addition, the effect of pressure on *n*-decane pyrolysis was quantitated using the equivalent temperature. Under the simulation conditions considered in the present study, each 1-MPa increase in pressure produced the same conversion as a temperature decrease of 6.5–10 K. In order to extrapolate the kinetic model to a wider range of pressure conditions, a model extrapolation method based on the activation volume was proposed.

In another modeling approach for the thermal cracking of hydrocarbon fuels at supercritical pressures, the thermal cracking process was treated as an infinite number of continuous microreactions at different fuel conversions, in which the stoichiometric coefficients of each species were expressed by continuous differentiable functions of the fuel conversion to consider the effects of secondary reactions [337]. A set of thermal cracking experimental results involving *n*-decane was used as an example to show

how to establish the differential global reaction model with variable stoichiometric coefficients. The differential global reaction model was implemented in a computational fluid dynamics simulation to predict *n*-decane thermal cracking coupled with flow, heat transfer, and wall thermal conduction in a cooling channel. The results showed that the differential global reaction model could more accurately predict the species mass fractions than existing global reaction models, especially for conditions when the secondary reactions strongly impact the thermal cracking. The stoichiometric coefficients of the differential global reaction model determined from the thermal cracking experiments only required the species mass/molar fractions. Therefore, the modeling method can be easily extended to other hydrocarbon fuels.

### 9.2.2 Catalytic Decomposition of *n*-Decane

*n*-Decane decomposition, an endothermic reaction, can be accelerated by catalysts. MoO<sub>3</sub>/Pt/CeO<sub>2</sub>/Al<sub>2</sub>O<sub>3</sub> composite oxides with various MoO<sub>3</sub> content were prepared and used for *n*-decane cracking under supercritical conditions [338]. The experiments showed that the catalyst with 8.3 mass-% MoO<sub>3</sub> exhibited the highest catalytic cracking activity among all catalysts, leading to a gas yield increased by 14.6% at 973 K (700 °C), and the heat sink capability increased by 0.39 MJ/kg compared with thermal cracking.

Monometallic and bimetallic Pt/Ni catalysts supported on La<sub>2</sub>O<sub>3</sub>-Al<sub>2</sub>O<sub>3</sub> modified by MoO<sub>3</sub> were evaluated for catalytic cracking of *n*-decane [339]. The results showed that the bimetallic catalyst had better catalytic cracking activity than other catalysts and exhibited the best high-temperature stability. The cracking activity of the bimetallic catalyst was due to unique acidity, higher resistance against sintering of active phases, finely dispersed active metals, enhanced metal-support interaction and synergistic effects between Pt and Ni.

## 10 *n*-Dodecane

*n*-Dodecane, C<sub>12</sub>H<sub>26</sub>, CAS RN [112-40-3], is an oily hydrocarbon with properties very similar to those of rocket propellants RP-1 and RP-2. When formulating surrogate hydrocarbon mixtures simulating RP-1 or RP-2, *n*-dodecane was often chosen as the third most prevalent hydrocarbon in the synthetic mixture. Because *n*-dodecane is a key component of RP-1 and RP-2, it is important to have a complete set of properties for the pure compound in order to identify the contributions this constituent makes to the hydrocarbon mixtures. If certain physical properties for RP-1 or RP-2 are not available in text books or from the literature, the next best option to not having any properties at all is to use the properties of *n*-dodecane as a substitute for those real-life hydrocarbon mixtures. This is the reason why this book contains a fairly detailed summary of the properties of this hydrocarbon.

## 10.1 Preparation of *n*-Dodecane

*n*-Dodecane and many other C<sub>12</sub> alkanes are constituents of petroleum distillates derived from crude oil by either distillation or cracking.

## 10.2 Physical Properties of *n*-Dodecane

The physical properties of *n*-dodecane are summarized in Table 39.

**Table 39:** Physical properties of *n*-dodecane.

| Property                                         | SI units                                   | Other units                                                  | References |
|--------------------------------------------------|--------------------------------------------|--------------------------------------------------------------|------------|
| Molecular mass                                   | 170.3348 g/mol                             | 5.8708 mol/kg                                                | [45]       |

| Critical volume                                  | 1.3 ± 0.1 mol/L                            | 0.287 g/cm <sup>3</sup>                                      |            |

### 10.2.1 Density of *n*-Dodecane

The density of *n*-dodecane as a function of temperature under saturation pressure conditions is shown in Figure 35.

**Figure 35:** Density of *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

### 10.2.2 Compressibility and Velocity of Sound of *n*-Dodecane

The velocity of sound in liquid *n*-dodecane as a function of temperature is shown in Figure 36.

The compressibility factor of *n*-dodecane,  $Z = P/\rho RT$ , is derived from velocity of sound measurements. As one can see in Figure 37, its trend is the opposite of that of the velocity of sound.

**Figure 36:** Velocity of sound in liquid *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

**Figure 37:** Compressibility factor of liquid *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

### 10.2.3 Vapor Pressure of *n*-Dodecane

The vapor pressure of *n*-dodecane as a function of temperature is illustrated in Figure 38.

**Figure 38:** Vapor pressure of *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

The vapor pressure of *n*-dodecane can be calculated from the Antoine equation

$$\log P = A - B/(T + C) = 6.109514 - [1628.949/(T - 92.4917)]$$

where  $P$  is the vapor pressure in kPa and  $T$  is the temperature in kelvin [314].

Another Antoine equation for the temperature range 400–490 K gives the vapor pressure of *n*-dodecane as

$$\log P = A - B/(T + C) = 4.10549 - [1625.928/(T - 92.839)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin (NIST).

### 10.2.4 Viscosity of *n*-Dodecane

Viscosity measurements have been made on nine pure hydrocarbon liquids, including dodecane, at six temperatures ranging from 288 to 408 K (15 to 135 °C) and at pressures as high as 4000 bars [340]. The dynamic viscosity of *n*-dodecane under saturation pressure conditions as a function of temperature is illustrated in Figure 39.

**Figure 39:** Dynamic viscosity of *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

Correlations for the viscosity and thermal conductivity of *n*-dodecane that are valid over a wide range of fluid states were developed based on surveyed literature data [341]. The new correlations were applicable from the triple point (263.59 K) to 800 K, and at pressures up to 200 MPa. The viscosity correlation had an estimated uncertainty of 0.5% along the saturation boundary in the liquid phase, 3% in the compressed liquid region, and 3% in the vapor (where the uncertainties can be considered as estimates of a combined expanded uncertainty with a coverage factor of 2). The thermal conductivity correlation had an estimated uncertainty of 4% along

the liquid saturation boundary and in the compressed liquid, and ~5% in the vapor region.

The dynamic viscosities of *n*-dodecane were measured at temperatures between 303 and 693 K and pressures up to 10 MPa using a dual-capillary viscometer [342]. The accuracy of the dual-capillary viscometer was improved by considering centrifugal effects and the thermal expansion of the capillary. The combined relative standard uncertainty in the dynamic viscosity was 0.58–2.92%. This study provided new data for checking the accuracy of Huber's correlations at supercritical pressures, and a small portion of the data points at supercritical conditions where few experimental data had been reported so far. The average absolute deviation between the experimental data and the calculated data from Huber's correlations was 0.97%, and the maximum absolute deviation was 6.79%. In the near-critical and supercritical region, the accuracy of viscosities of *n*-dodecane needs more experimental data for verification and to extend the theories.

### 10.2.5 Surface Tension of *n*-Dodecane

The surface tension of *n*-dodecane as a function of temperature (under saturation pressure conditions) is illustrated in Figure 40.

**Figure 40:** Surface tension of *n*-dodecane as a function of temperature. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

### 10.2.6 Thermal Conductivity of *n*-Undecane and *n*-Dodecane

This particular publication is for undecane and not for dodecane but it is referenced here because the physical properties of the two hydrocarbons are very similar. Assael et al. presented wide-ranging correlations for the viscosity and thermal conductivity of *n*-undecane based on critically evaluated experimental data [343]. The correlations

were designed to be used with an equation of state that is valid from the triple point to 700 K, at pressures up to 500 MPa, with densities below  $776.86 \text{ kg/m}^3$ . Both correlations behaved in a physically reasonable manner when extrapolated to the full range of the equation of state, but care must be taken when using the correlations outside of the validated range. The uncertainties will be larger outside of the validated range and also in the critical region.

The thermal conductivity of *n*-dodecane under saturation pressure conditions is illustrated in Figure 41.

**Figure 41:** Thermal conductivity of *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

## 10.2.7 Thermodynamic Properties of *n*-Dodecane

### 10.2.7.1 Heat Capacity of *n*-Dodecane

The heat capacity  $c_p$  of *n*-dodecane as a function of temperature under saturated conditions is illustrated in Figure 42. This property is required for calculating heat transfer and fuel temperature rise in cooling channels of rocket engines. The curves for heat capacities of liquid and vapor dodecane under saturation conditions are close together and then increase abruptly as they approach the critical temperature.

An equation of state has been developed to represent the thermodynamic properties of all liquid, vapor and supercritical states of *n*-dodecane [344]. Experimental data used to develop the equation included pressure-density-temperature state points, vapor pressures, isobaric and saturation heat capacities, heats of vaporization, and velocities of sound. The uncertainties of properties calculated using the equation were: 0.2% in density at pressures up to 200 MPa, and 0.5% at higher pressures up to 500 MPa; 1% in heat capacity; 0.5% in the velocity of sound; and 0.2% in vapor pressure. Deviations of calculated properties from available experimental data in the critical region were higher for all properties except for vapor pressure.

**Figure 42:** Heat capacity  $c_p$  of *n*-dodecane. (Image created by Schmidt 2020 based on data from National Institute of Standards and Technology RefProp.)

#### 10.2.7.2 Enthalpy of Vaporization of *n*-Dodecane

The heat of sublimation of *n*-dodecane is 100.2 kJ/mol at 298 K and 101.7 kJ/mol at 263 K. The enthalpy of vaporization of *n*-dodecane at 298 K was reported to be  $61.52 \pm 0.62 \text{ kJ/mol} = 361 \text{ kJ/kg}$  (Nelson and Chickos [326]). The enthalpy of vaporization of *n*-dodecane under saturation pressure conditions as a function of temperature is illustrated in Figure 43. The enthalpy of vaporization drops to near zero as the temperature approaches the critical point, the same as is observed for most fluids.

**Figure 43:** Enthalpy of vaporization of *n*-dodecane. (Image created by Schmidt 2020 based on data from NIST RefProp.)

### 10.2.8 Physical Properties of *n*-Dodecane Mixtures

RP-1 and RP-2 are hydrocarbon mixtures containing *n*-dodecane. *n*-Dodecane has been mixed with other hydrocarbons to make surrogate fuels with properties similar to those of RP-1 or RP-2 [345].

## 10.3 Chemical Properties of *n*-Dodecane

### 10.3.1 Thermal Decomposition of Dodecane

Although pure dodecane is not used as a rocket fuel, its thermal decomposition has been thoroughly investigated because it is a constituent of RP-1 and RP-2 and many other kerosene blends. The thermal cracking of *n*-dodecane was investigated using additives [346].

Pseudo-first-order-rate constants for the decomposition of *n*-dodecane at 623 and 673 K were measured in a batch reactor pressurized to 9.2 MPa (91 atm) with nitrogen or hydrogen [347]. Dodecane is thermally stable below 600 K, whereas under more severe conditions it is thermolyzed to give a series of paraffins and olefins up to C<sub>22</sub>, but with C<sub>13</sub> missing. High-pressure reaction favors the formation of saturated hydrocarbons and shifts the product distribution toward heavier components. The yield of paraffin plus olefin of the same carbon number decreased with increasing molecular weight, and the yield of the olefin was slightly higher than that of its paraffin counterpart. These observations can be interpreted by a free-radical-chain mechanism with certain modifications. Hydrogen participates in dodecane thermolysis reactions through radical-capping reactions. The pseudo-first-order rate law applies to dodecane disappearance.

In a study of the vapor-phase thermolysis of several straight-chain alkanes and their mixtures, including C<sub>9</sub>, C<sub>12</sub>, C<sub>13</sub>, C<sub>16</sub>, and C<sub>22</sub>, in a flowing tube reactor at atmospheric pressure and temperatures from 623 to 893 K, the thermolysis of unbranched alkanes yielded a series of 1-alkenes as major products [14]. The 1-alkene selectivity strongly depended upon pressure: the lower the pressure, the higher the selectivity.

Micro-reactor studies of *n*-dodecane decomposition rates in nitrogen at pressures of 0.69 to 1 MPa (6.8 to 9.9 atm) and temperatures of 673 to 723 K were carried out as part of an evaluation of hydrogen donors as stabilizers that would retard the decomposition of kerosenes [348, 349]. The most important conclusion of this work was that within the temperature range 673–723 K (400–450 °C), 1,2,3,4-tetrahydroquinoline (THQ) was by far the best thermal stabilizer that had been discovered up to that time and it was significantly more effective than benzyl alcohol.

Kinetics of the thermal decomposition of C<sub>10</sub>–C<sub>14</sub> *n*-alkanes and their mixtures was studied under near-critical and supercritical conditions [16]. Supercritical-phase thermal decomposition of *n*-alkanes can be represented well by an apparent first-order kinetics, even though the decomposition was not a true first-order process. A generalized expression was developed to predict the apparent first-order rate

constants for the decomposition of  $C_8$ - $C_{16}$  *n*-alkanes at 698 K (425 °C). Pressure had a significant effect on the apparent first-order rate constant in the near-critical region. This large pressure effect can be attributed to the significant changes in density and possibly to the changes in the rate constants of elementary reactions with pressure in the near-critical region. Individual compounds interacted with each other in the thermal reaction of *n*-alkane mixtures. The overall first-order rate constants for decomposition of *n*-alkane mixtures can be predicted satisfactorily from the rate constants for pure compounds.

Solid coke deposits from thermal stressing of a jet fuel model compound, *n*-dodecane, were studied in the presence of three initiator additives, 1-nitropropane (NP), triethylamine (TEA), or 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane (TEMPO), to show the role of initiators in the carbon deposition during the thermal cracking of jet fuels [350]. It was found that the thermal cracking rate of *n*-dodecane was enhanced by the initiators in the following order, TEMPO > NP > TEA, and that TEMPO and TEA remarkably inhibited the formation of pyrolytic deposits by 30–50% at a similar conversion level. Temperature-programmed oxidation of deposits indicated that reactive deposition can be reduced slightly by TEMPO and TEA, but the less reactive deposits are reduced because of possible radical scavenging or the hydrogen donation effect, resulting from the decomposition of TEMPO and TEA. Scanning electron microscopy (SEM) showed that TEA and NP also have a significant effect on the deposit morphologies. Those same results were also observed in the thermal stressing of Chinese RP-3 fuel with initiators.

Various additives were tested in the hope that they would prevent the formation of carbonaceous deposits during thermal stressing of hydrocarbons at high temperatures (>773 K = >500 °C) [351]. Three hydrogen donors, tetralin (THN),  $\alpha$ -tetralone (THNone), and benzyl alcohol, and two organic selenides, diphenyl selenide ( $Ph_2Se$ ) and diphenyl diselenide ( $Ph_2Se_2$ ), as well as their mixtures, were selected as thermally stable additives to inhibit the deposition from the thermal stressing of *n*-dodecane and Chinese RP-3. It was found that the amount of solid deposits from thermal stressing of RP-3 was reduced by 77.0% with the additive of  $Ph_2Se_2$ /THN/THNone. It was found that hydrogen donor THN/THNone and organic selenides possibly reduce the carbon deposits by retarding the thermal cracking rate, blocking surface catalysis, and depressing the reactivity of sulfur with the surface metals, as well as their synergistic effect. The morphologies of deposits also dramatically changed after adding organic selenides or hydrogen donors.

An experimental and computer modelling study of the pyrolysis of *n*-dodecane used a stainless steel isothermal plug flow reactor at temperatures of 950, 1000, and 1050 K and atmospheric pressure, with GC analysis of the end products showing mainly methane, ethane, and alkenes from  $C_2$  to  $C_{10}$  [352]. A detailed kinetic model containing 1175 reactions has been produced using EXGAS software. This model was able to represent with reasonable accuracy the experimental results, both for the

conversion of *n*-dodecane and for the formation of products, as well as literature data obtained from other sources measured at 623 to 823 K.

The thermal decomposition of *n*-dodecane was measured in a jet-stirred reactor at temperatures from 773 to 1073 K, with residence times between 1 and 5 s and at atmospheric pressure [353]. The products of the reaction were mainly hydrogen, methane, ethane, 1,3-butadiene, and 1-alkenes from ethene to 1-undecene. For higher temperatures and residence times acetylene, allene, propyne, cyclopentene, 1,3-cyclopentadiene, and aromatic compounds from benzene to pyrene through naphthalene have also been observed. A previously published detailed kinetic model of the thermal decomposition of *n*-dodecane generated using EXGAS software has been improved and completed by a sub-mechanism explaining the formation and the consumption of aromatic compounds.

A two-wavelength, mid-IR optical absorption diagnostic was developed for simultaneous temperature and *n*-dodecane vapor concentration measurements in an aerosol-laden shock tube. Shock tube studies of the high-temperature (1100 to 1300 K) decomposition of *n*-dodecane were completed within the pressure range 0.3 to 6 atm [354]. Fourier transform infrared absorption spectra for the temperature range 323 to 773 K were used to select the two wavelengths (3409 and 3432 nm). Shock-heated mixtures of *n*-dodecane vapor in argon were then used to extend absorption cross-section data at these wavelengths to 1322 K. At high temperatures, pseudo-first-order decomposition rates were extracted from time-resolved concentration measurements, and data from vapor and aerosol shocks were found to be in good agreement. Notably, the *n*-dodecane concentration measurements exhibited slower decomposition than predicted by models using two published reaction mechanisms, illustrating the need for further kinetic studies of this hydrocarbon. These results demonstrated the potential of multi-wavelength mid-IR laser sensors for hydrocarbon measurements in environments with time-varying temperature and concentration.

Supercritical additive-promoted thermal cracking of a jet fuel model compound, *n*-dodecane, was studied in the presence of several sensitizing additives, such as 1-nitropropane, triethylamine, and 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane in view of improving the heat sink of jet fuel [355]. It was found that the remarkable promoting effects of the initiative additives on the cracking rates, compared with the thermal cracking of pure *n*-dodecane, were observed up to 20–150% in the following order: 1-nitropropane > 3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane > triethylamine. Comparisons of product distributions from the thermal cracking of *n*-dodecane with and without initiators indicated that initiator type had a slight effect on the selectivity of the gas products, but a non-negligible effect on the distributions of liquid products. Apparent first-order kinetics were used to describe the supercritical initiative thermal cracking of *n*-dodecane, and the apparent cracking activation energy of pure *n*-dodecane was 256.56 kJ/mol, which decreased to 185.80 kJ/mol by the addition of 1-nitropropane, 196.05 kJ/mol by the addition of

3,6,9-triethyl-3,6,9-trimethyl-1,4,7-triperoxonane, and 242.83 kJ/mol by the addition of triethylamine.

An HZSM-5 zeolite coating was applied to the inner surface of a microchannel reactor by a washcoating method to improve the cracking rate of supercritical hydrocarbon fuels [356]. Thermal or catalytic cracking of *n*-dodecane was experimentally investigated in the stainless steel microchannel reactor coated with HZSM-5 coatings under supercritical conditions ( $p > 4$  MPa,  $T > 723$  K =  $> 450$  °C). It was found that cracking of *n*-dodecane was enhanced more than 100% by HZSM-5 coatings in 30-min reaction test run durations at 798 and 823 K (525 and 550 °C), despite gradual deactivation of catalytic activity due to coke deposition from pyrolysis and acid-catalyzed reactions. Cokes deposited in the microchannels with and without HZSM-5 coating were characterized by SEM and temperature-programmed oxidation, indicating that HZSM-5 coating effectively reduced formation of filamentous cokes and damage on the micro channel surface by shielding surface metals, for as long as the temperature was higher than 873 K (600 °C) at least.

The initiation mechanisms and kinetics of pyrolysis and combustion of *n*-dodecane were investigated by using reactive molecular dynamics (ReaxFF MD) simulation and chemical kinetic modeling [357]. From ReaxFF MD simulations, it was found that the initiation mechanisms of the pyrolysis of *n*-dodecane proceeds mainly through two pathways: **(1)** the cleavage of C—C bonds to form smaller hydrocarbon radicals, and **(2)** the dehydrogenation reaction to form an H radical and the corresponding  $n\text{-C}_{12}\text{H}_{25}$  radical. Another pathway is the H-abstraction reactions by small radicals including H, CH<sub>3</sub>, and C<sub>2</sub>H<sub>5</sub>, which are the products after the initiation reaction of *n*-dodecane pyrolysis. ReaxFF MD simulations lead to reasonable Arrhenius parameters compared with experimental results based on first-order kinetic analysis of *n*-dodecane pyrolysis, even when the density/pressure effects on the pyrolysis of *n*-dodecane were analyzed. By appropriate mapping of the length and time from macroscopic kinetic modeling to ReaxFF MD, a simple comparison of the conversion of *n*-dodecane from ReaxFF MD simulations and that from kinetic modeling was performed. When studying the oxidation of *n*-dodecane by ReaxFF MD simulations, it was found that formaldehyde molecule is an important intermediate in the oxidation of *n*-dodecane, which has been confirmed by kinetic modeling, and ReaxFF leads to reasonable reaction pathways for the oxidation of *n*-dodecane. These results indicated that ReaxFF MD simulations can give an atomistic description of the initiation mechanism and product distributions of pyrolysis and combustion for hydrocarbon fuels, and can be further used to provide a molecular-based robust kinetic reaction mechanism for chemical kinetic modeling of hydrocarbon fuels.

High pressure *n*-decane and *n*-dodecane shock tube decomposition experiments were conducted to assist in the development of a Jet A surrogate kinetic model [358]. In the formulation of surrogate mixtures for Jet-A, *n*-decane or *n*-dodecane represents the normal paraffin class of hydrocarbons present in kerosene fuels. The experimental

work on both *n*-alkanes was performed in a heated high-pressure single-pulse shock tube. Experimental data on both *n*-decane and *n*-dodecane oxidation and pyrolysis were obtained for temperatures from 867 to 1739 K, pressures from 19 to 74 atm, reaction times from 1.15 to 3.47 ms, and equivalence ratios from 0.46 to 2.05, and  $\infty$ . Both *n*-decane and *n*-dodecane oxidation showed that the fuel decays through thermally driven oxygen-free decomposition under the conditions studied. This observation prompted an experimental and modeling study of *n*-decane and *n*-dodecane pyrolysis using a revised *n*-decane/*iso*-octane/toluene surrogate model. The surrogate model was extended to *n*-dodecane in order to facilitate the study of the species and the 1-olefin species quantified during the pyrolysis of *n*-dodecane and *n*-decane were revised with additional reactions and reaction rate constants modified by rate constants taken from the literature. When compared against a published generalized *n*-alkane model and the original and revised surrogate models, the revised (based on our experimental work) and extended surrogate model showed improvements in predicting 1-olefin species profiles from pyrolytic and oxidative *n*-decane and *n*-dodecane experiments.

An investigation of temperature-dependent products in the pyrolysis of helium-seeded *n*-dodecane, which represents a surrogate of the *n*-alkane fraction of JP-8, was performed in a high-temperature chemical reactor over a temperature range of 1200 to 1600 K at a pressure of 600 mm Hg, with *in situ* identification of the nascent products in a supersonic molecular beam using single photon vacuum ultraviolet photoionization coupled with the analysis of the ions in a reflectron time-of-flight mass spectrometer [359]. The initial decomposition products of *n*-dodecane, including radicals and thermally labile closed-shell species, were probed in experiments, which effectively excluded mass growth processes. A total of 15 different products were identified, such as molecular hydrogen,  $C_2$  to  $C_7$  1-alkenes,  $C_1$ – $C_3$  radicals, small  $C_1$ – $C_3$  hydrocarbons (acetylene,  $C_2H_2$ , allene,  $C_3H_4$ , methylacetylene,  $C_3H_4$ ), as well as the reaction products (1,3-butadiene, 2-butene) attributed to higher-order processes. Electronic structure calculations combined with RRKM/master equation of rate constants for relevant reaction steps showed that *n*-dodecane decomposes initially by a non-terminal C–C bond cleavage and produces a mixture of alkyl radicals from ethyl to decyl with approximately equal branching ratios. The alkyl radicals appear to be unstable under the experimental conditions and to rapidly dissociate either directly by C–C bond  $\beta$ -scission to produce ethene plus a smaller 1-alkyl radical with the number of carbon atoms diminished by two or via hydrogen shifts followed by C–C  $\beta$ -scission producing alkenes from propene to 1-nonene together with smaller 1-alkyl radicals. The C–C  $\beta$ -scission continues all the way to the propyl radical, which dissociates to methyl plus ethene. In addition, at higher temperatures, another mechanism can contribute, in which hydrogen atoms abstract hydrogen from  $C_{12}H_{26}$ , producing various *n*-dodecyl radicals and these radicals then decompose by C–C bond  $\beta$ -scission to  $C_3$  to  $C_{11}$  alkenes.

*n*-Dodecane was selected as a surrogate for kerosene and it was subjected to a series of thermal cracking experiments at supercritical pressure [360]. According to variations in chemical heat sink, fuel-conversion rate, and gas-production rate, the thermal cracking of *n*-dodecane was divided into three regions: primary, secondary, and severe. In the primary cracking region, the fuel-conversion rate was lower than 13%, and the liquid products contained only chain alkanes and alkenes. Owing to the mass fraction of main products being proportional to the fuel-conversion rate, a one-step global reaction kinetic scheme was constructed. The secondary cracking region was characterized by a rapidly increasing chemical heat sink, fuel-conversion rates, and gas-production rates with increasing fuel temperature, and the appearance of monocyclic aromatic hydrocarbons and cycloalkenes. A kinetic model containing three reactions was proposed for this region. This also considered the thermal decomposition of chain alkanes and alkenes, which resulted in the formation of monocyclic aromatic hydrocarbons and cycloalkenes. Severe cracking was observed for fuel-conversion rates above 71% where a rapid increase in the concentration of monocyclic and polycyclic aromatic hydrocarbons occurred. The increasing rate of chemical heat sink slowed in this region, which was characterized by the formation of monocyclic and polycyclic aromatic hydrocarbons and coke. A three-dimensional numerical model was built for the primary and secondary cracking regions, taking the effects of the flow, heat transfer, and thermal cracking of *n*-dodecane into consideration. Predicted values for the outlet temperature, fuel-conversion rate, and distribution of the main species in all tested cases agreed well with the experimental results, validating the numerical model and kinetics for the primary and secondary thermal cracking of *n*-dodecane.

### 10.3.2 Oxidation of *n*-Dodecane

Oxidation of *n*-dodecane may come from dissolved oxygen when in contact with air or in a rocket engine. Rocket engine operations with kerosenes will be discussed in a future volume on non-hypergolic bipropellant combinations. Here, we are only looking at some of the chemical kinetics of dodecane oxidation, in particular, some that may lead to the formation of soot (coke).

A single, compact, and reliable chemical mechanism was proposed that can accurately describe the oxidation of a wide range of fuels, which are important components of surrogate fuels for kerosenes [361]. A well-characterized mechanism appropriate for the oxidation of smaller hydrocarbon species and several substituted aromatic species, ideally suited as a base to model surrogates, has been extended to describe the oxidation of *n*-dodecane, which is often used in diesel and jet fuel surrogates. To ensure compactness of the kinetic scheme, a short mechanism for the low-to high-temperature oxidation of *n*-dodecane was extracted from a scheme detailed earlier and integrated in a systematic way into the base model. Rate changes based on rate recommendations from the literature were introduced to the resulting chemical

mechanism in a consistent manner, which improved the model predictions. Thorough validation of the revised kinetic model was performed using a wide range of experimental conditions and data sets.

Pyrolysis and oxidation kinetics of *n*-dodecane within the temperature range 1000–1300 K were investigated in a Variable Pressure Flow Reactor facility where the reactor environment is vitiated and the experiments were conducted at atmospheric pressure [362]. Species time-history data were collected for *n*-dodecane and oxygen, as well as for 12 intermediate and product species over a span of 1- to 40-ms residence times using real-time GC. The experimental data were compared against the predictions of four detailed kinetic models. The results showed that the hydrocarbon oxidation proceeds through an early pyrolytic stage, where the fuel breaks down into smaller hydrocarbon fragments, including mostly  $C_{2-4}$  alkenes, and a late oxidation stage where the fragments oxidize to CO. The kinetic models were observed to diverge notably in their predictions from one another. The flow reactor data were used to demonstrate how model uncertainty minimization can improve model predictions. It was shown that after uncertainty minimization against a selected set of *n*-dodecane combustion data, the predictions of the resulting optimized model were improved notably for all existing *n*-dodecane data sets tested, including those of the current flow reactor study that were not part of the optimization target list.

#### 10.4 Safety Properties of *n*-Dodecane

The average flash point of *n*-dodecane tested by several laboratories was 358 K (85°C) [363].

### 11 Hexadecane

Hexadecane, also known as cetane,  $C_{16}H_{34}$ , CAS RN [544-76-3] is a viscous oily hydrocarbon with a melting point of 291 K (18°C = 64°F) and a boiling point of 560 K (287°C = 549°F). The cetane number is a measure of the ease of ignition and combustion of diesel fuel by adiabatic compression. Cetane ignites very easily under adiabatic compression; for this reason, it was assigned a cetane number of 100, and serves as a reference for other fuel mixtures. Hexadecane is not used as a rocket propellant as such, but is a natural constituent of RP-1, RP-2, and many of the JP fuels.

#### 11.1 Physical Properties of Hexadecane

*n*-Hexadecane is a constituent of RP-1 and RP-2 and it is important to have physical properties for the pure compound before using it as a constituent of surrogate fuel

mixtures. A correlation for the viscosity of *n*-hexadecane was based upon a set of experimental data that had been critically assessed for internal consistency and for agreement with theory [3]. It is applicable within the temperature range from the triple point to 673 K at pressures up to 425 MPa and along the saturation line.

A wide-ranging correlation for the thermal conductivity of *n*-hexadecane based on critically evaluated experimental data was designed to be used with an equation of state, and covered a range from the triple point up to 700 K and pressures up to 50 MPa [364]. The correlation behaved in a physically reasonable manner when extrapolated to the full range of the equation of state, but the uncertainties are larger outside of the validated range, and deviations are large in the critical region.

## 11.2 Thermal Decomposition of Hexadecane

A pyrolysis reaction system that provided better control than the tubular flow reactors of previous researchers was used to study the ultrapyrolysis kinetics of *n*-hexadecane [365]. Ultrapyrolysis, or ultra-rapid pyrolysis, refers to thermal cracking under conditions of high temperatures, very short reaction times, high heating rates, and rapid product quench. Millisecond furnaces operating under such conditions have demonstrated significantly higher ethene yields owing to improved selectivity. The automated micro-reaction system used a Curie point pyrolyzer to rapidly heat microgram *n*-hexadecane samples to high temperatures. The Curie point phenomenon ensured that a reproducible and well-defined temperature was attained. A rapid direct quench system was used to stop the reactions and transfer the products to the analyzer. *n*-Hexadecane was pyrolyzed at 849–1115 K (576–842 °C) for 100–3200 ms. Peak ethene production (28 mass-%) was observed at ultrapyrolytic conditions of 1115 K (842 °C) and 500 ms. A first-order kinetic analysis performed on the pyrolysis data yielded an activation energy of 165 kJ/mol (39.4 kcal/mol).

Thermal cracking of *n*-hexadecane was carried out in a tubular flow reactor at 653–723 K (380–450 °C), 13.9 MPa, and residence times ranging from 0.06 to 2.0 h, giving conversions of 1.5–10% [366]. Primary reaction products were C<sub>1</sub> to C<sub>14</sub> *n*-alkanes and C<sub>2</sub> to C<sub>15</sub> α-olefins, in agreement with a free-radical chain mechanism. Under high-pressure conditions, addition of radicals to α-olefins became significant. Addition of parent hexadecyl radicals to α-olefins resulted in the formation of alkyl hexadecanes within the range C<sub>18</sub> to C<sub>31</sub>. Addition of lower primary alkyl radicals to α-olefins gave higher *n*-alkanes, including *n*-C<sub>15</sub> and *n*-C<sub>17</sub>. Addition of lower secondary alkyl radicals resulted in the formation of C<sub>7</sub> to C<sub>17</sub> branched alkanes. A simple kinetic model based on a free-radical mechanism was developed to account for the observed product distributions and overall *n*-C<sub>16</sub> conversion.

Thermal cracking of *n*-hexadecane within the mild temperature (603–648 K = 330–375 °C) range was investigated in liquid and gas phases [367]. The kinetics of liquid-phase cracking were shown to be very similar to those of gas-phase cracking.

However, the pattern and distribution of the products were greatly phase dependent. In liquid-phase cracking, there was an equimolar distribution of *n*-alkane and 1-alkene products within the  $C_3$ – $C_{13}$  range at low conversion. When the conversion was increased, more alkanes than alkenes were produced. To the contrary, more alkenes than alkanes were always determined in products from gas-phase cracking. Liquid-phase cracking gave a low selectivity of gas products and a high selectivity of addition compounds ( $C_{18}$ – $C_{30}$ ), whereas gas-phase cracking produced a large amount of gas products and no addition compounds. The phase dependence of products was interpreted in terms of a low concentration of hexadecane, under which  $\beta$ -scission would occur more preferentially than in the liquid phase. Reaction mechanisms were suggested based on the product analysis to account for the different cracking behaviors of liquid-phase and gas-phase cracking.

Pyrolysis experiments on *n*-hexadecane were conducted at 673–723 K and *n*- $C_{16}$  concentrations of 0.07–1.47 mol/L by using batch-type reactors [282]. The main products of *n*- $C_{16}$  pyrolysis were *n*-alkanes and 1-alkenes under all the reaction conditions. The 1-alkene/*n*-alkane ratio decreased with increasing *n*- $C_{16}$  concentration at all the reaction temperatures. The rate of *n*- $C_{16}$  pyrolysis increased to a maximum and then decreased with increasing *n*- $C_{16}$  concentration. The activation energy of the overall rate constant of *n*- $C_{16}$  pyrolysis was 196 kJ/mol at 0.07 mol/L of *n*- $C_{16}$  concentration and 263 kJ/mol at 0.22 mol/L. A mathematical model for the pyrolysis was developed to describe these phenomena and the radical network reaction, including initiation, isomerization,  $\beta$ -scission, H abstraction, and termination. The effect of radical size on the rates of bimolecular reactions (H abstraction and termination) was important for a correct quantitative description. Comparison between the experimental data and the model showed that the rates of bimolecular reactions were inversely proportional to the carbon number *i* of radical  $R_i$ . The model was able to predict product distribution and *n*- $C_{16}$  pyrolysis rates within a wide range of temperatures (603–893 K) and *n*- $C_{16}$  concentrations ( $6.86 \times 10^{-3}$  to 2.48 mol/L). The model can even describe the pyrolysis kinetics of *n*- $C_{10}$  to *n*- $C_{25}$  by considering the carbon number of the hydrocarbon.

## 12 Branched Chain Aliphatic Hydrocarbons

Branched chain hydrocarbons not only had better octane numbers for combustion in internal combustion engines in automobiles and airplanes (better than straight-chain molecules), but they were also expected to burn more smoothly (less combustion instabilities) in rocket engines. One of the synthetic branched-chain hydrocarbons considered as a replacement for RP-1 in ATLAS rocket engines was “tetraisobutylene” and its heat transfer properties were measured [368]. An analytical and experimental investigation was made of the heat-transfer characteristics of tetraisobutylene to determine the potential of this fuel as a replacement for RP-1 in an Atlas engine with FLOX oxidizer. Under regenerative cooling conditions of surface and fluid temperature, the

heat sink from the endothermic dissociation of this fluid could not be realized. Experiments also evaluated the heat-transfer characteristics of RP-1 at fluid temperatures over 422 K (300 °F).

Isobutylene can be polymerized and results in the formation of oily, liquid oligomers that can be separated by fractionated distillation or used as mixtures. Oligomers described in the literature include diisobutylene, triisobutylene, and tetraisobutylene [369]. Triisobutylene consists of a mixture of three isomers, 1,1-dineopentylethene, 1-methyl-1-neopentyl-2-*tert*-butylethene, and 1,1-dimethyl-2,2-di-*tert*-butylethene [370, 371].

Oligopropylenes, such as the trimer and the tetramer, had exceptionally high autoignition temperatures in air when tested in a spontaneous ignition test apparatus [372].

# Alkenes and Alkynes

## Introduction

The *Encyclopedia of Liquid Fuels* contains eight chapters that deal with hydrocarbon fuels. It was necessary to sub-divide the topic of hydrocarbon fuels into several smaller sections that were easier to arrange in alphabetical order in five subvolumes of equal size. The titles of the eight hydrocarbon chapters are: “Alkanes,” “Alkenes and Alkynes,” “Aromatic Hydrocarbons,” “Cycloaliphatic Hydrocarbons,” “Hydrocarbons,” “Jet Fuels,” “Kerosenes,” and “Ramjet Fuels.”

## 1 Unsaturated Hydrocarbons: Alkenes and Dienes

Alkenes, also called *olefins*, contain at least one carbon-to-carbon double bond, making them *unsaturated compounds*. The general formula for alkenes with one double bond is  $C_nH_{2n}$ . If they contain two, three, or more double bonds, they are called *dienes*, *trienes*, or *polyenes*, respectively. If the double bonds in a chain alternate with single bonds, they are termed *conjugated double bonds*. Such bonds share electron clouds, causing quantum mechanical resonance, which increases the thermal stability but also the reactivity of molecules containing conjugated double bonds. Alkenes with one or more double bonds are more susceptible than alkanes to autoxidation and resin formation, an undesirable property for jet engine fuels and rocket fuels alike. Alkenes with one or more double bonds are more reactive than either alkanes or aromatics, and their presence will reduce the storability of liquid fuels.

Depending on the application of the fuel, the presence or absence of double bonds is encouraged or avoided. In one wants a polyunsaturated hydrocarbon fuel capable of hypergolic ignition with WFNA or mixed acid, one looks for a molecule with many double bonds. If one wants a storable hydrocarbon fuel without resin formation due to autoxidation, one minimizes the content of double bonds.

The formation of double and triple bonds increases the enthalpy of formation of alkanes, as shown in Table 1. However, the loss of hydrogen may outweigh the gain in energy released when one applies the rocket propulsion specific impulse formula in the search for better rocket propellants.

The increased energy content of ethene increases the specific impulse of LOX/ethene over that of LOX/ethane or LOX/kerosene. The chamber temperature is hotter than the LOX/ethane flame.

Alkenes containing two or more conjugated double bonds may be reactive enough that they will ignite hypergolically with WFNA or RFNA or mixed acid, but they may also spontaneously polymerize and thus cannot be stored without forming resins that would clog orifices.

**Table 1:** Enthalpies of formation of alkanes, alkenes, and alkynes.

| Compound             | Enthalpy of formation, liquid |                | Enthalpy of formation, gas |               | References |
|----------------------|-------------------------------|----------------|----------------------------|---------------|------------|
|                      | kJ/mol                        | kcal/mol       | kJ/mol                     | kcal/mol      |            |

(calc.) indicates that this number was calculated by subtracting the enthalpy of vaporization from the enthalpy of formation of the vapor

The use of butadiene and substituted butadienes as hypergolic fuels in combination with WFNA or RFNA was patented, but has never found any application [4].

## 2 Ethene (Ethylene)

Ethene (ethylene) has gained importance as the fuel in pulse detonation engines, rotating detonation engines, and in monopropellant mixtures with nitrous oxide.

### 2.1 Production and Availability of Ethene

Ethene is an important feedstock for the chemical and polymer industry and is produced in megaton quantities by cracking petroleum in refineries.

## 2.2 Physical Properties of Ethene

Physical properties of ethene are summarized in [5, 6]. They are also listed in Table 2.

**Table 2:** Physical properties of ethene.

| Property                                | SI units                                  | Other units                                                   | References |
|-----------------------------------------|-------------------------------------------|---------------------------------------------------------------|------------|
| Molecular mass                          | 28.0532 g/mol                             | 35.6465 mol/kg                                                | [1]        |

### 2.2.1 Vapor Pressure of Ethene

The vapor pressure of ethene in the range 149–188 K can be calculated from the Antoine equation:

$$\log(P) = A - [B/(T + C)] = 3.87261 - [584.146/(T - 18.307)]$$

where  $P$  is the vapor pressure in bar and  $T$  is the temperature in kelvin.

### 2.2.2 Viscosity of Ethene

Data for the viscosity and thermal conductivity coefficients of gaseous and liquid ethene were evaluated and represented by polynomial empirical functions [8]. The data were represented in graphs as a function of density rather than as a function of temperature, which would have been more convenient. Tables of values were presented for the temperature range 110–500 K and for pressures up to 50 MPa (500 atm). The viscosity of liquid ethene at 165 K is 186.32 μPa s, and the viscosity of ethene gas at 298 K is 9.2398 μPa s.

### 2.2.3 Surface Tension of Ethene

Data for the surface tension of liquid ethene are summarized in Table 3.

**Table 3:** Surface tension of liquid ethene.

| Temperature, K | Surface tension, mN/m |
|----------------|-----------------------|
| 114.1          | 26.09                 |
| 115.8          | 25.76                 |
| 117.3          | 25.49                 |
| 119.1          | 25.09                 |
| 120.1          | 24.96                 |
| 121.7          | 24.65                 |
| 123.1          | 24.38                 |

Data source: [9]

The surface tension of liquid ethene as a function of temperature can be expressed by the equation

$$\eta = 47.68 - 0.1893T$$

where  $\eta$  is the surface tension in mN/m and  $T$  is the temperature in kelvin.

### 2.2.4 Thermal Conductivity of Ethene

Data for the thermal conductivity coefficients of gaseous and liquid ethene were evaluated and represented by polynomial empirical functions [8]. The data were represented in graphs as a function of density rather than as a function of temperature, which would have been more convenient. Tables of values were presented for the temperature range 110–500 K and for pressures up to 50 MPa (500 atm). The anomalous contribution to the thermal conductivity in the vicinity of the critical point was included. The thermal conductivity of liquid ethene at 165 K is  $191.95 \text{ mW m}^{-1} \text{ K}^{-1}$  and the thermal conductivity of ethene gas at 300 K is  $20.56 \text{ mW m}^{-1} \text{ K}^{-1}$ .

The thermal conductivities of ethene and propene were measured as a function of temperature and density from 110 to 520 K at pressures up to 200 MPa [10]. The resulting correlations were valid from 180 to 625 K and up to 50 MPa, but they also behaved in a physically reasonable manner down to the triple point and may be used at pressures up to 100 MPa. For both fluids, uncertainties in the critical region were very large, since the thermal conductivity approached infinity at the critical point and was very sensitive to small changes in density.

The thermal conductivity of ethene was measured in a coaxial cylinder cell operating under steady-state conditions along eight quasi-isotherms above the critical temperature over the temperature range from 283 to 425 K and the pressure range from 0.1 to 100 MPa [11].

### 2.2.5 Critical Constants of Ethene

The critical point properties of ethene are as follows:

$$T_c = 282.34 \text{ K}$$

$$\rho_c = 0.215 \text{ g/cm}^3 \quad (7.66 \text{ mol/L})$$

$$P_c = 5.0390 \text{ MPa} \quad (49.73 \text{ atm})$$

$$M = 28.054$$

### 2.2.6 Thermodynamic Properties of Ethene

Fundamental equations for the thermodynamic properties of ethene from the freezing line to 450 K and at pressures up to 260 MPa included independent equations for the vapor pressure of the saturated liquid and vapor densities as functions of temperature, and for the ideal gas heat capacity [12, 13]. The coefficients of the fundamental equation were determined by a weighted least-squares fit to selected  $P - \rho - T$  data and saturated liquid and saturated vapor density data to define the phase equilibrium criteria for coexistence,  $C_v$  data, velocity of sound data, and second virial coefficient data. The fundamental equation and the derivative functions were used to calculate the internal energy, enthalpy, entropy, isochoric heat capacity ( $C_v$ ), isobaric heat capacity ( $C_p$ ), and velocity of sound. Tables of thermodynamic properties of ethene were assembled for liquid and vapor states within the range of validity of the fundamental equation.

## 2.3 Chemistry of Ethene

### 2.3.1 Reactions of Ethene

Ethene is capable of polymerizing under a variety of conditions. The most important polymerization process is the synthesis of polyethylene, the most widely used plastic foil for packaging and building materials. Precautions should be taken during the storage and transport of liquid ethene to avoid catalytic contaminants [14].

### 2.3.2 Analysis of Ethene

The easiest method of performing occasional spot checks of the ethene concentration in air in the workplace is to use gas detection tubes made from glass tubes containing an indicator (supported on a granular material) that changes color when exposed to ethene. Such tubes are available from Draeger, MSA, Kitagawa, and others. Gas detection tubes are sensitive to as little as 0.2 ppm  $\text{C}_2\text{H}_4$  and can measure up to 2500 ppm  $\text{C}_2\text{H}_4$  with ten strokes. Draeger ethene gas detection tubes are available for two ranges of concentrations (Table 4).

**Table 4:** Draeger ethene gas detection tube concentration ranges.

| Tube designation | Concentration range | Draeger part number |
|------------------|---------------------|---------------------|
| Ethene 0.1/a (5) | 0.2–5 ppm           | 81 01 331           |
| Ethylene 50/a    | 50–2500 ppm         | 67 28 051           |

Data source: [15]

## 2.4 Safety Properties of Ethene

### 2.4.1 Limits of Flammability of Ethene

The limits of flammability of ethylene in oxygen, air, and air/nitrogen mixtures were measured at elevated temperatures and pressures in a 3 L spherical bomb [16]. The limits in oxygen were determined at 353, 393, and 423 K (80, 120, and 150 °C) and over the pressure range 932–3550 kPa (135–515 psia). The limits in air and air/nitrogen mixtures were determined at 101, 310, and 932 kPa (14.7, 45, and 135 psia) and at 293 and 523 K (20 and 250 °C). The upper limit in oxygen was raised by increasing either the temperature or pressure, but the effect of the pressure was small above 2.07 MPa (300 psia). The upper limit in air was also raised by increasing either temperature or pressure, and the critical oxygen concentration was reduced under the same conditions. Explosions in oxygen/ethylene mixtures close to the upper limit of flammability at high pressures gave abnormally high explosion pressures. This effect was attributed to the energy released by the decomposition of ethylene and the formation of significant quantities of methane.

Mixtures of ethylene with small amounts of oxygen are used as the feed for the synthesis of ethylene oxide, but these mixtures are potentially flammable. The flammabilities of oxygen/ethylene mixtures with different diluents (nitrogen, carbon dioxide, methane) were measured at up to 523 K (250 °C) and 2.03 MPa (20 atm) [17].

The upper flammability limit of ethene/air/nitrogen mixtures under flow conditions was measured with the gas mixtures flowing through an explosion tube with a length of 3.0 m and a diameter of 21 mm [18]. An electrically heated wire was used as the ignition source. Experiments were performed at pressures of 5 and 10 bar, with gas temperatures between 298 and 573 K (25 and 300 °C), and with the ignitor wire oriented horizontally and vertically. Three different phenomena were observed: a negligible reaction, a local reaction, and an explosion. The negligible reaction region occurred at power supply rates to the wire below a critical value. Above this critical value, either a local reaction or an explosion took place. The critical oxygen concentration that separated the local reaction and explosion regimes depended on the experimental conditions used (i.e., the gas composition, pressure, temperature, wire size and orientation, and gas velocity). An increase in pressure increases the upper flammability limit. Obviously, the upper flammability limit is influenced by the gas velocity. Under flow conditions, the explosion region becomes smaller and shifts to higher oxygen con-

centrations. This is important for applications in the chemical industry that depend on partial oxidation reactions of ethylene.

#### 2.4.2 Critical Diameter for the Propagation of Air/Ethene Explosions

Knowledge of the critical diameter for the propagation of detonations is required for the design of flame arrestors and detonation arrestors. The critical diameter is the tubing or orifice diameter below which detonation from a donor section cannot propagate into an acceptor section of detonable gas [19]. A series of field tests was performed to obtain the critical tube diameter ( $d_c$ ) for air/ethylene mixtures by investigating the diffraction of detonations from tubes into large plastic bags simulating an unconfined fuel/air cloud. The critical air/ethylene compositions for successful re-establishment of detonation upon emerging from tubes with diameters of 0.31, 0.45, 0.89, and 1.36 m were determined by monitoring the diffracted detonation wave in the bag. High-speed cinematography of the diffracted wave showed that re-establishment of detonation occurs via one or more re-ignition centers at sites along the head of the expansion wave that originates at the area change. The characteristic transverse wave spacings,  $S$ , associated with the detonations were measured from smoked foils mounted in the tubes. These measurements demonstrated that the empirical relation  $d_c = 13S$  provided a good correlation between the critical tube diameter and the cell size over a wide range of ethylene/air compositions. Based on these tests, it was concluded that the critical tube and critical orifice diameters are equal.

A similar experimental study has been carried out to investigate the transmission of a planar detonation wave through an orifice into an unconfined medium [20]. Mixtures of  $C_2H_4 + 3(O_2 + \beta N_2)$  for a range of nitrogen concentrations corresponding to  $1 \leq \beta \leq 3.76$  and at an initial pressure of 1 atm were used in the experiments. It was found that the critical diameter for transmission through an orifice is identical to that for a straight tube and that both follow the empirical correlation of  $d_c \cong 13\lambda$ . Transmission through square, triangular, elliptical, and rectangular orifices has led to the development of a correlation based on the effective diameter similar to that for a circular geometry (i.e.,  $d_{eff} \cong 13\lambda$ ). The effective diameter is defined as the mean value of the longest and shortest dimensions of the orifice shape.

#### 2.4.3 Critical Initiation Energy for Air/Ethene Explosions

Critical initiation energy results for a range of air/hydrocarbon mixtures are shown in Figure 1. This graph presents a comparison of critical initiation energy data for the air/ethene system derived from the experiments of Murray et al. [21] with more recent data obtained by Guirao, Knystautas, and Lee [22]. The agreement between both sets of data is good. This information would be useful for the design of pulsed detonation engines or rotating detonation engines that operate on air/ethene.

**Figure 1:** Variation of the critical energy for the direct initiation of spherical detonation with the fuel percentage in ethylene/air mixtures at NTP. (Reproduced and modified from Figure 15 of [22].)

#### 2.4.4 Deflagration-to-Detonation Transitions in Air/Ethylene Gas Mixtures

A series of single-shot experiments were conducted to characterize the deflagration-to-detonation transition (DDT) of air/ethene mixtures in a 45 × 45-mm square tube that was 1.65 m long [23]. Obstacles are important for inducing the DDT; this fact can be used advantageously in pulse detonation engines.

### 3 Propene (Propylene)

Propene (C<sub>3</sub>H<sub>6</sub>, CAS RN [115-07-1]) has been selected as a rocket propellant fuel by Vector Launch Inc. of Tucson, AZ in 2018. It was to be used as the fuel in combination with LOX for its planned Vector-R and Vector-H launch vehicles. Very little is known about their rationale for selecting propene over propane or kerosene. Prior to that, propene had been considered as a fuel to use in combination with hydrogen peroxide [24].

### 3.1 Physical Properties of Propene

The physical properties of propene are summarized in Table 5.

**Table 5:** Physical properties of propene.

| Property                                       | SI units                                  | Other units                                  | References |

## 4 Acetylene and Acetylene Derivatives

Acetylene and acetylene compounds (*alkynes*) contain at least one triple bond between two carbon atoms,  $\text{—C}\equiv\text{C—}$ , and have the general formula  $\text{C}_n\text{H}_{2n-2}$ . The name acetylene is specifically used to designate the simplest member of the series, also known as ethyne ( $\text{C}_2\text{H}_2$ ;  $\text{HC}\equiv\text{CH}$ ). Acetylene and many acetylene compounds have very high enthalpies of formation and very high heats of combustion, making them suitable fuels to reach very high flame temperatures but not necessarily high specific impulses unless a hydrogen carrier is added to the formulation.

The CH group adjacent to a triple bond in acetylene or terminal alkynes is more acidic than any other hydrocarbon bond and can form stab-sensitive explosive metal salts with silver or copper.

Instead of physically dissolving acetylene in other fuels, it has been proposed that high-energy fuels could be synthesized by introducing the alkyne group  $\text{—C}\equiv\text{CH}$  as a substituent into other hydrocarbons, amines, or hydrazines. Alkyne molecules with one or two attached nitrile groups have extremely high flame temperatures (see the chapter “Cyano Compounds and Nitriles” in *Encyclopedia of Liquid Fuels*).

It has also been proposed that alkyne groups could be introduced into solid propellant binders to give them more energy [26, 27].

Although the primary objective was to develop fuels for air-breathing turbo jet engines or bipropellant rocket systems, tests by other laboratories indicated that acetylenic hydrocarbons also have interesting possibilities for monopropellant and ramjet engine systems [28]. Some of the acetylenic compounds investigated are listed in Table 6.

**Table 6:** Properties of acetylene derivatives.

| Compound                                                               | Density<br>at 293 K | Melting point |       | Boiling point      |                     | Net heat of<br>combustion |        |

Data source: [28]

The most promising of these compounds appeared to be dimethyl divinyl diacetylene, which rendered JP-4 hypergolic with both WFNA and RFNA when present in concentrations as low as 15% by volume. Methyl divinyl acetylene also appeared quite promising, since it exhibited excellent low-temperature ignition characteristics. Methyl divinyl acetylene had an ignition delay of 5.5 ms at 219 K (-65 °F) with RFNA as the oxidizer, while the ignition delay of triethylamine was 29 ms in the same apparatus. The cap sensitivities of the acetylenic compounds were tested with 10-mL samples in a glass test tube inserted into a lead pipe. Exploding compounds were incrementally diluted with hexane until the no-detonation point was reached. Insensitive acetylenic compounds were sensitized by the incremental addition of

peroxy butane until the mixture became sensitive. Dimethyl divinyl diacetylene showed greater sensitivity than peroxy butane.

Cyclopropylacetylene has a density of  $0.773 \text{ g/cm}^3$  at 293 K. Dipropargylether has a density of  $0.924 \text{ g/cm}^3$  at 293 K. Deterioration of acetylenic compounds during storage is mainly caused by polymerization and peroxidation. In general, acetylenic compounds that are not conjugated and contain no double bonds are the most stable. A series of tests have been run to determine the relative stabilities of many of the acetylenic compounds. Samples were heated at 344 K (71 °C) for 5 days and were then analyzed for polymer content [29]. A variety of propargyl compounds have been evaluated as high energy density materials [30].

## 4.1 Acetylene

Acetylene itself ( $\text{HC}\equiv\text{CH}$ ,  $\text{C}_2\text{H}_2$ , ethyne, CAS RN [74-86-2]) can be liquefied only under extreme precautions. Liquid acetylene is very explosive and it is not suitable for use as a rocket propellant [31]. Interestingly, solutions of acetylene in liquid ammonia are stable enough and have been tested as rocket propellants. We therefore give a summary of the properties of acetylene below, even though this chemical will not be used as a rocket propellant in the pure state.

### 4.1.1 Production of Acetylene

Acetylene is easily produced by reacting calcium carbide with water. Prior to the availability of acetylene in compressed gas cylinders with a solvent, it was common practice to have calcium carbide acetylene gas generators at metalworking shops where oxygen/acetylene welding torches were used.

### 4.1.2 Physical Properties of Acetylene

The physical properties of acetylene are summarized in Table 7.

**Table 7:** Physical properties of acetylene.

| Property                                   | SI units                | Other units    | References |
|--------------------------------------------|-------------------------|----------------|------------|
| Molecular mass                             | 26.0373 g/mol           | 38.4064 mol/kg | [1]        |

| Critical pressure                          | 61.38 ± 0.10 bar        | 890 psia       |            |
| Critical volume                            | 0.1122 L/mol            | —              |            |

### 4.1.3 Chemical Properties of Acetylene

#### 4.1.3.1 Thermal Decomposition of Acetylene

The thermal decomposition of acetylene usually proceeds with explosive force, so it is difficult to obtain kinetic rate information unless the reactive gas is highly diluted. The thermal decomposition of acetylene is used on an industrial scale for producing very pure carbon black called acetylene black. In theory, the reaction proceeds as the reverse of the formation of acetylene from the elements:

Under real-life conditions, the decomposition products contain ethylene and methane.

The pyrolysis of acetylene/argon mixtures has been investigated in the temperature range 1400–2500 K using shock wave heating [32]. Time-resolved emission and absorption spectra, measurements of reflected shock velocities, and an analysis of the products of the reaction have been used to follow the rate of loss of acetylene. The average activation energy over the temperature range from 600 to 2500 K was approximately 163 kJ/mol (39 kcal/mol), and there is evidence that the same mechanism is dominant over the entire range of temperatures.

The activation energies of first- and second-order acetylene decomposition reactions in acetylene/argon mixtures in shock tube experiments were 109 and 138 kJ/mol (26 and 33 kcal/mol), respectively [33].

#### 4.1.3.2 Reactions of Acetylene

Acetylene is a weak acid and, as such, forms salts with strong bases. Sodium acetylide is relatively stable, but silver acetylide is very shock and friction sensitive, similar to silver azide and lead azide.

In an attempt to prepare acetylide salts of strong organic bases as propellant ingredients, solutions of sodium acetylide in liquid ammonia were reacted with guanidinium(1+) sulfate or tetramethylammonium chloride, but the only products were the sodium salts and acetylene gas. The affinity of the acetylide anion for protons was higher than its affinity for organic base cations [34, 35].

Instead of synthesizing acetylides, they were successful in synthesizing salts of propiolic acid (acetylene carbonic acid), such as tetramethylammonium propiolate  $\text{HC}\equiv\text{C}-\text{COO}[\text{N}(\text{CH}_3)_4]$  [36]. The melting point of the salt in a sealed capillary tube was 408 K (135 °C). Decarboxylation of the salt did not yield any tetramethylammonium acetylide, only the evolution of acetylene. The presence of an acetylenic function was demonstrated by the formation of a precipitate when ammoniacal silver nitrate was added to an aqueous solution of the compound.

#### 4.1.4 Detonation of Acetylene in the Absence of Air

It has been shown that explosive acetylene decomposition may occur in the deflagration mode and detonation mode. The term deflagration is understood to refer to flame propagation at variable velocity, depending on the operating conditions. Acetylene can detonate in the liquid or gaseous state even in the absence of air. The detonation of air/acetylene mixtures will be discussed in the chapter “Non-hypergolic Combinations with Oxygen” in a future volume to be published as a part of the *Encyclopedia of Rocket Propellants*. In acetylene, the formation of a detonation wave and energy release are due to the condensation of supersaturated carbon vapor rather than exothermic oxidation reactions, in contrast to most other gas detonation processes. The detonability of acetylene increases sharply with pressure. Acetylene compressed to pressures above 60 atm combusts spontaneously.

##### 4.1.4.1 Detonation of Liquid Acetylene

The detonability of liquid acetylene severely limits the use of acetylene as a fuel gas and feedstock for chemical syntheses because it cannot be stored safely in the liquid state. See Section 4.1.7.3.

##### 4.1.4.2 Detonation of Gaseous Acetylene

Older sources reported that the lower pressure detonation and combustion limits of gaseous acetylene were considerably above 1 atm, and that the upper detonation limit of acetylene/oxygen mixtures at 1 atm was 92 vol.-% acetylene. It was later shown that stable detonations can occur at much lower pressures and at much higher acetylene concentrations. It was found that, depending upon the diameter of the detonation tube, 1–3 g of high explosive such as tetryl will initiate a stable detonation wave in acetylene at an initial pressure as low as 80 kPa (60 cm Hg) [37].

The observed velocity of detonation in acetylene gas initially at 8 atm was found to be  $1817 \pm 7$  m/s in a 12-mm (0.5-in.) diameter pipe and  $1870 \pm 22$  m/s in a 25-mm (1.0-in.) diameter pipe [38]. These results led to an estimate of 1923 m/s for the limiting velocity at infinite diameter. A theoretical value of 2053 m/s was calculated from the Chapman–Jouget theory of detonation. The properties of detonation waves in compressed acetylene were therefore found to be substantially in accord with theory, although there was a discrepancy of 130 m/s between the measured and calculated velocity. Possible reasons for this discrepancy were discussed.

Experiments in small-diameter tubes under pressure indicated an inverse relationship between tube diameter and the critical pressure of detonation wave propagation in gaseous acetylene [39]. With tubes 3 and 8 mm in diameter, the critical pressures were 22.5 and 16 atm, respectively. Exceeding these critical pressures by 1 atm would lead to detonation propagation in acetylene in 50% of cases; exceeding them by 4 atm would lead to propagation in 90% of the tests.

In a study of the mechanism of the explosive decomposition of acetylene it was found that the particle size of the carbon formed by the explosive decomposition of

acetylene in tubes at pressures above atmospheric pressure increased as the propagation rate of the flame front increased [40]. This was explained by heat losses through emission from the front. A study relating the acetylene decomposition temperature to the particle size of the carbon formed used an injection method where a portion of acetylene was introduced into a previously heated evacuated volume, and the gaseous and solid products were examined after decomposition.

In many cases, the process of acetylene decomposition is accompanied by superhigh pressures that are 300–400 times higher than the initial pressure of the gas. An experimental investigation of transient flame modes of acetylene decomposition was conducted to explain the superhigh pressures and to list conditions for DDT transient regimes [41]. The experiments were performed in rectangular tubes with cross-sections of  $219 \times 8.5$ ,  $120 \times 10$ , and  $75 \times 13$  mm and lengths of 124, 36, and 32.6 m, respectively. Explosive acetylene decomposition was initiated at the tube end by heating a Nichrome wire. The reaction zone traversed the last third of the tube with a velocity of 250–333 m/s. In sufficiently long tubes this process transitions to detonation.

The detonation of acetylene is sustained by the energy derived from the condensation of carbon. The formation of a condensation detonation wave has been experimentally observed in the shock-induced thermal decomposition of acetylene. A stable detonation wave in a 20%  $C_2H_2$ /80% Ar mixture was obtained at an initial pressure behind the shock wave of no less than 30 atm [42]. The main kinetic characteristics of the pyrolysis of acetylene – the period of the induction of condensation and the growth rate constant of condensed particles – have been determined. Condensation stages characterized by significant heat release occur very rapidly (faster than  $10^{-5}$  s) in so-called explosive condensation. An analysis of the results indicated that the reactions leading to the growth of large polyhydrocarbon molecules, which precede the formation of condensed carbon particles, constitute the limiting stage of the process that determines the possibility of the formation of the condensation detonation wave in acetylene. An increase in pressure was accompanied by a sharp narrowing of the induction region and a transition of the process to the condensation detonation wave.

The initiation energy required to initiate acetylene explosive decay is dependent on the amount of water vapor present. Hydrogen peroxide vapor has a similar effect [43]. In an analysis of kinetic data using theoretical concepts regarding the dominant role of chain processes in gas combustion, it was concluded that water vapor and hydrogen peroxide vapor can have a promoting effect on the explosive decomposition of acetylene. This prediction contradicted earlier conclusions that were based on the thermal theory of combustion, which stated that water can only exert a diluting effect on acetylene decomposition. More recent experiments confirmed that it is possible to initiate acetylene decomposition in the presence of water vapor or hydrogen peroxide at an ignition energy 100 times lower than that of the explosive decomposition of dry acetylene at atmospheric pressure. Other data in the literature indicated that acetylene explosiveness is largely determined by humidity.

#### 4.1.5 Speed of Acetylene Decomposition Flames

The burning velocity of acetylene decomposition flames increased markedly with pressure in the range 202–1013 kPa (2–10 atm) [44]. Neither the straightforward burning velocity vs pressure plot nor the corresponding log-log plot gave a tolerably straight line, so there appears to be no simple analytical expression relating burning velocity and pressure for this flame. The burning velocity data for acetylene and methylacetylene are summarized in Table 8. The quenching diameter of the acetylene flame at 205 kPa (2.02 atm) was approximately 0.6 cm. The measured brightness temperature of the acetylene decomposition flame at 10 atm was 2140 or 3160 K assuming that no energy is lost as radiation.

**Table 8:** Burning velocities of acetylene and methylacetylene decomposition flames.

| Fuel                   | Acetylene |      |      |      |      | Methylacetylene |      |      |
|------------------------|-----------|------|------|------|------|-----------------|------|------|
| Pressure, atm abs.     | 2.02      | 4.06 | 6.10 | 8.14 | 10.2 | 10              | 20   | 40   |

Data source: [44]

A method of stabilizing a pure acetylene decomposition flame on a burner over a range of temperatures and pressures has been developed [45]. Its safety depends on the use of a specialized flow and compressor system. The variation of the burning velocity with temperature and pressure was determined not only for acetylene but also for a series of air/hydrocarbon mixtures in order to test both the apparatus and the method of interpretation. The tasks were: (1) to develop a flow system that terminates in a burner, will meter and deliver acetylene safely at a range of pressures and temperatures over which the gas can decompose spontaneously, and prevents flashback; (2) to develop a burner on which an acetylene decomposition flame can be stabilized in a form suitable for accurate burning velocity measurements at a range of pressures and temperatures; and (3) to determine burning velocities at various temperatures and pressures for several air/hydrocarbon mixtures and then for acetylene by itself. An analysis of the acetylene decomposition results yielded effective orders and activation energies that differed substantially from those of low-temperature pyrolysis as well as shock-tube studies. A proposed reaction mechanism, which is likely to be dominant only in the presence of flames and the absence of soot deposits, accounts for these differences as well as for the numerical values obtained. In the presence of soot, an alternative heterogeneous surface reaction is likely to become important. Based on the dependence of burning velocity on the inlet gas temperature, with decomposition at pressures be-

tween 2.5 and 3.3 atm and burning velocities of between 7.3 and 16.6 cm/s, an activation energy of 90.4 kJ/mol (21.6 kcal/mol) was proposed for a first-order reaction.

Acetylene decomposition flame propagation was numerically analyzed and was found to be the result of a condensation reaction. Condensation processes provide reaction heat and act as a driving force for  $C_2H_2$  flame propagation. Some kinetic models can predict the burning velocity of the acetylene decomposition flame, but the model did not demonstrate the relatively strong positive pressure dependence of burning velocity observed experimentally [46]. Heat-release kinetics indicated a two-stage process. The first stage corresponds to heat release due to the formation of benzene and other polyaromatics, and the second stage of heat release corresponds to soot inception and carbonization processes. It was demonstrated that the burning velocity is sensitive to the surface growth rate constant. The use of a simplified presentation of the surface growth process explained the positive thermal feedback in the heat generation in the flame reaction zone.

#### **4.1.5.1 Speed of Acetylene Combustion Flames**

Flame speeds and critical diameters for the propagation of acetylene combustion flames in air or oxygen will be discussed in more detail in a future chapter “Non-hypergolic Combinations with Oxygen.” Often these flames are characterized using the same type of equipment used for acetylene decomposition flames.

#### **4.1.6 Handling of Acetylene**

Chemical reactions involving acetylene under pressure are extremely dangerous and must be carried out with all necessary safety precautions. A system has been designed for experiments with liquid acetylene under pressure [47].

#### **4.1.7 Safety Properties of Acetylene**

##### **4.1.7.1 Flammability Limits of Acetylene in Air**

The flammable range of acetylene in air is 2.5–100 vol.-%. The autoignition temperature is 578 K (305 °C).

##### **4.1.7.2 Ignition Energy for Acetylene Decomposition**

The critical pressure for the decomposition of acetylene initiated by a melting platinum wire at 288 K (15 °C) was reported as 1.4 bar. Later, when an initiation energy of 1200 J was used instead of 1 J, the critical pressure dropped to 0.65 bar from 1.6 bar. A more powerful chemical igniter that provided 2400 J was able to initiate the propagation of acetylene decomposition at pressures as low as 0.54 bar [48].

##### **4.1.7.3 Detonability of Acetylene**

Accidental detonation of acetylene has been the cause of numerous industrial accidents.

A plan to load supercritical acetylene into a sounding rocket and release it into the stratosphere to study the chemiluminescence of the reaction between acetylene and atomic oxygen was proposed. To assess the feasibility of loading supercritical acetylene into a large tank and releasing it at high rates, samples of supercritical acetylene with densities in the range from 0.208 to 0.256 g/cm<sup>3</sup> (13–16 lb/cu.ft) were subjected to high temperature, explosive shock, mechanical shock, ignition by flame, and rapid venting operations [49]. The results of these tests showed that supercritical acetylene presents no more of an explosive hazard than TNT and that sounding rocket experiments could be made with supercritical acetylene loaded into a payload tank.

#### 4.1.8 Acetylene Fuel Mixtures

Acetylene/ethane mixtures with only a few percent oxygen have been patented as gun propellants [50]. The main fraction of the energy released is derived from the decomposition of acetylene, with the oxygen only aiding in the ignition.

Alkylhydrazines are good solvents for acetylene when acetylene needs to be removed from a gas stream [51].

In 2012 it was reported that the Russian rocket engine manufacturer Energomash had started the development of a new rocket engine that could vastly reduce the cost of rocket launches and avoid the need to produce cryogenic hydrogen for fuel. Instead, the rocket was described as using “a completely novel fuel mixture of acetylene and ammonia (*atsetam*).” The properties of acetylene/ammonia mixtures are described in detail in the chapter “Ammonia” in *Encyclopedia of Liquid Fuels*.

Ammonia and acetylene are miscible over the entire range of compositions. Ammonia is a protophilic compound of average basicity, while acetylene is a proton-donating compound with weakly acidic character. The hydrogen that forms the hydrogen bond between the two molecules comes from the acetylene and not from the ammonia, and extends from the acetylene molecule to the free electron pair on the nitrogen atom. Spectral analysis revealed that acetylene binds to ammonia through a weak hydrogen bond (C—H...N) to form a C<sub>3v</sub>-symmetric top, consistent with previous microwave and IR spectroscopic studies at 3 μm. The acetylene/ammonia system shows small negative deviations from Raoult’s law. Such deviations, as foreseen, increase as the temperature decreases and must be ascribed to both chemical and physical ammonia–acetylene interactions.

##### 4.1.8.1 Physical Properties of Acetylene Mixtures

The objective when developing acetylene/fuel mixtures is to find a mixture that is less detonable than acetylene by itself but still benefits from the high energy contributed by the C≡C triple bond. Ideally, the added fuel should be rich in hydrogen such that acetylene raises the heat of combustion and the added fuel lowers the mean molecular weight of the exhaust products, resulting in a better specific impulse of the mixture.

Prior to considering them as rocket fuels, ammonia/acetylene mixtures were used as solvents for acetylene in organic synthesis reactions where the use of undiluted acetylene might constitute an explosion hazard [47]. Vapor–liquid equilibrium data on the acetylene/ammonia system for seven isotherms in the range 213–298 K (–60 to +25 °C) and at 1–32 atm were measured and interpreted according to the thermodynamics of associated systems. It was shown that thermodynamic consistency could be achieved by assuming the formation of a bimolecular complex between acetylene and ammonia. Equilibrium constants for this complex in the liquid phase were derived and related to the corresponding gas-phase values known from the literature.

Ammonia/acetylene fuel mixtures had been burned with oxygen in the laboratory, but no rocket engine tests were documented prior to the Russian studies. The theoretical rocket performance of LOX/NH<sub>3</sub>-C<sub>2</sub>H<sub>2</sub> combinations was calculated [52]. We are looking forward to reading reports that this propellant combination has actually flown.

Acetylene is very soluble in *N*-methylpyrrole and similar *N*-alkylpyrroles, and such solutions could be used as rocket fuels [53]. The Bunsen coefficient (the volume of gas at 101 kPa and 273 K per volume of solvent) of acetylene in *N*-methylpyrrole is 7.3. In the petroleum industry, *N*-methylpyrrole can be used to selectively wash acetylene from a product gas mixture. Such solutions would be hypergolic rocket fuels with WFNA or RFNA used as the oxidizer.

## 4.2 Methylacetylene

One of the better-characterized alkynes is methylacetylene (propyne, H<sub>3</sub>C–C≡CH, C<sub>3</sub>H<sub>4</sub>, CAS RN [74-99-7]). In the liquid state, it is not quite as sensitive as liquid acetylene. In either case, one must avoid the formation of metal acetylides.

It has been stated that although methylacetylene has a high monopropellant specific impulse and a high fuel specific impulse, it suffers from the disadvantages of having a high vapor pressure and a low density. One way of overcoming these difficulties would involve blending methylacetylene with other high-energy compounds that have low vapor pressures. The vapor pressures of a number of blends were calculated according to Raoult's law, and the monopropellant specific impulses were calculated for blends that have vapor pressures of 413 kPa (60 psia) at 311 K (100 °F).

### 4.2.1 Production of Methylacetylene

Methylacetylene and certain diolefins, such as allene, can be made by the thermal cracking of branched chain monoolefins, in particular isobutylene [54, 55]. Isobutane mixtures containing steam are heated for 0.05–0.5 s at 1073–1173 K (800–900 °C) and about 101 kPa (1 atm) of pressure, then cooled rapidly to give allene and methylacetylene. Yields are highest at limited (e.g., 28%) conversions.

Hydrocarbons of the acetylene and cyclopropane families, by virtue of their extra energy, yield fuels that have higher specific impulses and increased reactivity (resulting in smoother combustion in engines) than conventional rocket or aviation fuels. Possible methods of producing such fuels were reviewed, and several commercial processes were described [56]. One fuel of interest was 2-methyl-1,5-hexadiene-3-yne [57].

A mixture of 30% 2,7-dimethyl-1,7-octadiene-3,5-diyne in 2-methyl-1-butene-3-yne has good ignition properties, low thermal and shock sensitivities, and a low freezing point ( $<233\text{ K} = <-40^\circ\text{F}$ ) [58].

Allene can be isomerized to methylacetylene at  $425\text{--}683\text{ K}$  ( $150\text{--}410^\circ\text{C}$ ) in the presence of alumina. Allene is passed over  $\text{Al}_2\text{O}_3$  at  $483\text{ K}$  ( $210^\circ\text{C}$ ) at a space velocity of  $825\text{ h}^{-1}$  to make methylacetylene [59]. Allene and methylacetylene can be made by the catalytic conversion of isobutylene and propylene [60].

#### 4.2.2 Physical Properties of Methylacetylene

The physical properties of methylacetylene are summarized in Table 9.

**Table 9:** Physical properties of methylacetylene.

| Property                                   | SI units                                   | Other units                                     | References |
|--------------------------------------------|--------------------------------------------|-------------------------------------------------|------------|
| Molecular mass                             | 40.0639                                    | 24.9601 mol/kg                                  | [1]        |
| Freezing point                             | $170.2 \pm 0.6\text{ K}$                   | $-102.9^\circ\text{C}$                          |            |
| Boiling point                              | $250.0 \pm 0.5\text{ K}$                   | $-23^\circ\text{C}$                             |            |
| Density                                    | $0.6711\text{ g/cm}^3$ at $248.9\text{ K}$ | $0.6711\text{ g/cm}^3$ at $-24.2^\circ\text{C}$ | [29]       |
| Vapor pressure                             | 507 kPa at $293\text{ K}$                  | 5 atm at $20^\circ\text{C}$                     |            |
| Enthalpy of formation, gas                 | $+185.4 \pm 0.88\text{ kJ/mol}$            | $+44.3 \pm 0.2\text{ kcal/mol}$                 | [1]        |
| Enthalpy of formation, liquid              | $+162.4\text{ kJ/mol}$ (calc.)             | $+38.8\text{ kcal/mol}$                         |            |
| Enthalpy of vaporization at $242\text{ K}$ | $23.0\text{ kJ/mol}$                       | $5.50\text{ kcal/mol}$                          |            |
| Critical temperature                       | $402.4 \pm 0.2\text{ K}$                   | $129.3 \pm 0.2^\circ\text{C}$                   | [1]        |
| Critical pressure                          | $56.3 \pm 0.2\text{ bar}$                  | $817 \pm 3\text{ psia}$                         |            |
| Critical volume                            | $0.1635\text{ L/mol}$                      | —                                               |            |

#### 4.2.3 Chemical Properties of Methylacetylene

##### 4.2.3.1 Thermal Decomposition of Methylacetylene

Methylacetylene may self-decompose under certain conditions. Methylacetylene has been investigated as a monopropellant, but has never found application as such [61] (see the chapter “Organic Monopropellants” in *Encyclopedia of Monopropellants*).

Theoretically, the decomposition reaction proceeds as the reverse of the formation of methylacetylene from the elements:

Under real-life conditions, the decomposition products contain ethylene, methane, and a little ethane.

#### 4.2.3.2 Burning Velocity of Methylacetylene Decomposition Flames

The burning velocity of methylacetylene decomposition flames is listed in Table 8 above. The burning velocity of the methylacetylene flame varies little, if at all, in the range 1–4 MPa (10–40 atm) [44]. The quenching diameter of the methylacetylene decomposition flame at 1 MPa (10 atm) is less than 0.3 cm.

#### 4.2.4 Safety Properties of Methylacetylene

The lower limit of methylacetylene combustion in air with upward propagation is 1.7 vol.-%. This is an extremely low lower limit. The upper limit is 100%. Methylacetylene will burn in the absence of air, which is why it is considered a monopropellant.

##### 4.2.4.1 Toxicity of Methylacetylene

Rats were exposed to average concentrations of 42000 ppm methylacetylene for 6 h in an acute toxicity test, and rats and dogs were exposed to 28700 ppm 6 hours a day, 5 days a week for 6 months in chronic tests [62]. Exposure to the acute concentration resulted in almost complete anesthesia in all the animals within 95 min. The majority of the animals had recovered completely 40 min after the cessation of exposure. Exposure to the chronic concentration caused the dogs to lose weight during the first 6 weeks of exposure, after which they regained their initial weight. Both levels of exposure produced ataxia, mydriasis, salivation, and anesthesia, and it was noted that the response to exposure became less severe in dogs. With rats, the most significant sign of toxicity was death, which occurred in 8 out of 20 animals.

In Europe, the MAK of 1000 ppm was based on an earlier TLV of 1000 ppm, but this was later repealed [63].

##### 4.2.4.2 Explosive Hazards of Methylacetylene

Undiluted liquid methylacetylene is shock sensitive and will explode if heated rapidly [64]. Construction materials that come into contact with methylacetylene must not contain any copper.

The adiabatic compression sensitivities of several monopropellants, including methylacetylene, were tested in a rapid compression test apparatus where a gas bubble in contact with the propellant was compressed rapidly by a gas-driven piston [65]. The mass and velocity of the piston were analogous to the mass and velocity of a slug of liquid propellant flowing in a propellant feed system against a dead-end pipe. The minimum compressive energy per gas bubble volume required to initiate propellant decomposition was used as the safety criterion. The most sensitive sample tested was a mixture of ethyl nitrate and propyl nitrate ( $4.8 \pm 0.8$  kg-cm/mL). Methylacetylene was made to decompose with bubble volumes of 0.8 and 0.4 mL.

For those tests, the liquid sample was loaded at 233 K ( $-40^{\circ}\text{C}$ ) and fired at 243 K ( $-30^{\circ}\text{C}$ ). Decompositions were indicated by the presence of a compacted carbon pellet in the sample holder. The sensitivity of methylacetylene was only marginal,  $86 \pm 12 \text{ kg}\cdot\text{cm}/\text{mL}$  (Figure 2).

**Figure 2:** Adiabatic compression sensitivity of methylacetylene. (Republished and modified from Figure 12 on page 197 of [65] with permission from the American Institute of Aeronautics and Astronautics; permission was conveyed through Copyright Clearance Center Inc.)

## 4.2.5 Combustion of Methylacetylene

### 4.2.5.1 Flammable Range of Methylacetylene in Air

The lower limit of flammability of methylacetylene in air is 1.7 vol.-% [66]. There is no upper limit because methylacetylene will decompose even in the absence of air or oxygen.

#### 4.2.5.2 Explosive Sensitivity of Methylacetylene

The adiabatic compression sensitivity of methylacetylene was tested in an adiabatic compression sensitivity tester developed by Aerojet and compared to those of *n*-propyl nitrate, nitromethane, and a mixture of 60% ethyl nitrate/40% propyl nitrate [65]. The apparatus consisted of a pneumatically driven piston that rapidly compressed a gas bubble above a liquid propellant sample. In a few cases, the apparatus was also inverted, pushing the liquid upward into the gas (vapor) bubble. The sensitivity was expressed in terms of the piston kinetic energy divided by the size of the gas bubble, which is the slope of a straight line separating the go from the no-go areas in an *x-y* chart. The results are summarized in Table 10. In this series of tests, methylacetylene was the least sensitive chemical, so it required the highest compression energy to initiate an explosion.

**Table 10:** Adiabatic compression sensitivity of methylacetylene in comparison to those of other monopropellants.

| Compound                                        | Adiabatic compression sensitivity, $\text{kg cm mL}^{-1}$ |
|-------------------------------------------------|-----------------------------------------------------------|
| Methylacetylene                                 | $86 \pm 12$                                               |
| Mixture of 60% ethyl nitrate/40% propyl nitrate | $4.0 \pm 0.8$                                             |
| <i>n</i> -Propyl nitrate                        | $6.7 \pm 1.2$                                             |
| Nitromethane                                    | $10.4 \pm 1.7$                                            |

Data source: [65]

In a series of detonability tests in heavy-walled confined tubes with unsymmetrical dimethylhydrazine (UDMH), nitromethane, ethylene oxide, and methylacetylene, only nitromethane detonated completely [67].

#### 4.2.6 Applications of Methylacetylene

Methylacetylene had been evaluated as a fuel for a helicopter with blades propelled by tip-mounted ramjets [68–70].

Range calculations were made for a long-range air-breathing missile that employed a ram rocket as the power plant [71]. The ram rocket power plant was adapted to the structure of the TRITON missile, a ramjet with a range of 2000 miles and a baseline design that used JP-1 as a fuel. Methylacetylene was used to illustrate potential fuel improvements. The results of the investigation indicated that the ram rocket could achieve the same range as the rocket-boosted ramjet with a lower total take-off weight.

#### 4.2.7 Properties of Methylacetylene Mixtures

Methylacetylene/propane/propadiene (MAPP) gas is a stabilized mixture of methylacetylene and propadiene. Alkane and alkene hydrocarbons are added as stabilizers. The stabilizers serve to render the methylacetylene and propadiene shock insensitive and ensure that their concentrations remain nearly uniform at all times during the vaporization of the mixture. MAPP gas is transported and stored as a liquid under its own vapor pressure. Its transportation, storage, and handling characteristics are the same as those of liquefied petroleum gas. It has a characteristic odor that is detectable at concentrations as low as 100 ppm in air. Stabilized liquefied MAPP liquid and MAPP gas vapor are insensitive to shock [72].

Rats, guinea pigs, rabbits, and dogs were exposed 7 h per day, 5 days per week for a period of 16 weeks to either 5000 or 1000 ppm of a mixture of saturated and unsaturated C3 and C4 hydrocarbons (MAPP Industrial Gas<sup>®</sup>) [73]. There were no adverse effects on either sex of any species exposed to 1000 ppm, as determined by growth, mortality, body and organ weights, clinical and biochemical determinations, urinalysis, hematological examination, and gross and microscopic pathological examination. Results of a limited sensory perception study of humans indicated that some persons could detect 25 ppm and most would detect 100 ppm. The odor was found to be strong at 1000 ppm and quite objectionable at higher concentrations.

The flammable limits of MAPP gas in air are 2 and 13 vol.-%. MAPP/air mixtures have been evaluated as fuel/air explosives.

#### 4.3 Diacetylenes

Several dialkylbutane-1,3-diyne fuels have been patented and are considered to be hypergolic with IRFNA [74]. Examples of this type of fuel are shown below:

1,4-Dicyclopropyl-1,3-butadiyne, 4-Cyclopropylbuta-1,3-diynylcyclopropane

1-Cyclobutyl-4-cyclopropyl-1,3-butadiyne, 4-cyclopropylbuta-1,3-diynylcyclobutane

1,4-Dicyclobutyl-1,3-butadiyne, 4-cyclobutylbuta-1,3-diynylcyclobutane

1-Methyl-4-cyclopropyl-1,3-butadiyne, 1-Cyclopropylpenta-1,3-diyne, Penta-1,3-diynylcyclopropane

1-Ethyl-4-cyclopropyl-1,3-butadiyne, Hexa-1,3-diynylcyclopropane

The compound shown first is 1,4-dicyclopentyl-1,3-butadiyne (CAS RN [114546-62-2], empirical formula  $C_{10}H_{10}$ , formula weight 130.19 g/mol).

Compounds that contain several acetylene linkages in the molecule are called oligoalkadiynes. Macrocyclic oligoalkadiynes have been synthesized [75]. Apart from strong electronic interactions, spirocyclopropanated macrocyclic oligodiacetylenes are also highly energetic compounds. When struck too powerfully with a spatula, the samples decompose immediately, forming a cloud of black soot.

#### 4.4 1,7-Octadiyne

Octadiyne ( $C_8H_{10}$ , CAS RN [871-84-1]) has been tested with LOX as the oxidizer in a side-by-side comparison with RP-1 in a 220-N (50-lbf) rocket engine [76]. Its density is 1.8% less than that of RP-1, and its specific impulse is 3% better than RP-1.

##### 4.4.1 Physical Properties of 1,7-Octadiyne

The boiling point of 1,7-octadiyne at atmospheric pressure is 408–409 K (135–136 °C). The density at 294 K is 0.817 g/cm<sup>3</sup>. The flash point is at 296 K (23 °C). The index of refraction  $n_D^{20}$  is 1.4464. The standard enthalpy of formation is +334 kJ/mol (+79.9 kcal/mol). The heat of combustion is 44.85 MJ/kg (19297 BTU/lb).

# Alkylboranes

## Introduction

Alkylboranes share many properties, such as pyrophoricity, with their parent compounds, the inorganic boranes described in *Encyclopedia of Liquid Fuels* chapter “Boranes.” Their parent element, boron, is described in chapter “Boron.” Alkylboranes, boranes and elemental boron all share the common disadvantage of diboron trioxide deposition in the combustion products, possibly leading to clogged orifices and nozzle throats.

## 1 Alkylboranes

Alkylboranes, also called boron alkyls, are compounds where the alkyl groups are directly bound to the central boron atom by way of a C–B bond [1–3]. Alkylpentaboranes and alkyldecaboranes were manufactured on a large scale in the past but are no longer in use. Similar to the chapter on fluorine compounds as rocket propellants, this chapter on alkylboranes is now mostly of historical interest. A detailed write-up in book format of the US borane effort covering the years from 1950 to 1965 is the most comprehensive summary ever published on this exciting period of borane fuel development [4]. A subsequent anecdotal and historical account of the US borane program written by an experienced insider makes very entertaining reading [5]. We wish that there were similar easy-to-read books on the history of some of the other rocket propellants, such as the early years of hydrazines and hydrogen peroxide.

Hydrogen atoms in diborane can be gradually replaced by alkyl groups to form alkylidiboranes. After replacing more than four of the hydrogen atoms in diborane by alkyl groups, there are not sufficient hydrogen atoms to maintain the hydrogen bridge between the two boron atoms, and the molecule splits into fragments that contain only one boron atom per molecule. These are called alkylboranes instead of alkylidiboranes.

Alkylboranes and alkyl aluminum compounds will probably not be used as main rocket propellants, but they have been used as ignition aids for the hypergolic slug ignition of bipropellant rocket engines with non-hypergolic oxidizers such as LOX. They have also been evaluated as fuels in air-breathing ramjets or afterburners.

The different types of alkylboranes where R is an alkyl group (most often an ethyl group that can be attached by reacting boranes with ethylene) are listed below:

|                                |                                                  |
|--------------------------------|--------------------------------------------------|
| Alkylboranes (boron trialkyls) | $\text{BR}_3$                                    |
| Alkylidiboranes                | $\text{B}_2\text{H}_{(6-n)}\text{R}_n \ (n < 4)$ |
| Alkylpentaboranes              | $\text{B}_5\text{H}_{(9-n)}\text{R}_n$           |
| Alkyldecaboranes               | $\text{B}_{10}\text{H}_{(14-n)}\text{R}_n$       |

In 1952, the United States started a major effort to develop *high-energy fuels* (HEF) or *exotic fuels* as replacements for common kerosene jet fuels under the code name ZIP. These compounds were intended to have much higher heats of combustion and could burn at lower pressures, thus giving airplanes greater ranges and allowing them to fly at higher altitudes (out of reach of the enemy's interceptor fighter jet planes at that time) [6, 7].

These fuels were prepared by the alkylation of diborane with subsequent pyrolysis, or by the pyrolysis of diborane to pentaborane(9) and decaborane(14) with subsequent alkylation of these products. A whole family of alkylborane fuels was investigated that were generally referred to by code names assigned by the Air Force: HEF-1 (ethylidiborane), HEF-2 (propylpentaborane), HEF-3 (ethyldecaborane), HEF-4 (methyldecaborane), and HEF-5 (ethylacetylenedecaborane). The HEF fuel that was produced in the largest quantities was HEF-3. Another family of boron fuels were known as Hi-Cal fuels. The Air Force's program was largely devoted to HEF-3. The B-70 (XB-70) design originally used the J93-GE-5 engine with HEF-3 in the afterburners fed from separate fuel tanks. The General Electric J93 jet engine used on the B-70 and F-108 was designed to use HEF-3 in its afterburner section only. This avoided some of the main problems with HEF. By burning it only in the afterburners, the problem with oxide slag buildup on the turbine blades was eliminated, and since the afterburners were only used for takeoff and high-speed flight, the problems with the exhaust were greatly reduced. However, this meant that the advantages of using HEF-3 were also greatly reduced as it was used only part of the time instead of all the time. By using it for only one portion of the engine, and only during certain portions of the flight regime, the range was only extended by about 10%. There were also studies on the use of HEF-3 in the BOMARC ramjets, as well as studies into its use by the US Navy's aircraft carrier fleet to power high-performance aircraft, but these programs all died out and were discontinued. In the end, the problems with burning HEF throughout the entire turbojet engine turned out to be impossible to solve. At best, the HEF fuels could be used in the afterburner. Removing the oxide buildup on the turbine blades and housing was difficult. These issues, combined with the high cost of producing the fuel and its toxicity issues, seriously hampered the competitiveness of HEF-ZIP fuel. In 1959, the Air Force eventually canceled the boron fuel program altogether, after which it found only small-scale use as a rocket fuel. These fuels never saw flight applications. The expensive boron fuel production plants were first mothballed and eventually dismantled without ever having operated at full capacity [8, 9].

## 2 Trialkylboranes

The most frequently used term for  $\text{BR}_3$  compounds is trialkylboranes. Occasionally they are also called boron trialkyls or trialkylboron compounds. The name trialkylboron could be used in analogy to trialkylaluminum. Very rarely, the term trialkyl-

alane is used for those aluminum compounds. Also, in the antiquated literature, one might also find the use of the term trialkylborine.

Boron is trivalent in all of its organic compounds. Trialkylborane compounds with small alkyl groups are pyrophoric in air and can be used as ignition fluids with LOX and other non-hypergolic combinations. They have not been used as the main rocket fuel.

Trimethylborane or boron trimethyl,  $(\text{CH}_3)_3\text{B}$ , is a colorless gas at room temperature which ignites spontaneously in air. It has the shortest ignition delay of all trialkylboranes.

Triethylborane or boron triethyl,  $(\text{C}_2\text{H}_5)_3\text{B}$ , is a colorless liquid at room temperature. It ignites instantly as soon as air comes into contact with the liquid and burns with a beautiful green flame (truly a “green” propellant). Mixtures of triethylborane and triethylaluminum are used as hypergolic slug ignition fluids for rocket engines, with LOX used as the oxidizer. One of the launch vehicles that uses this mode of ignition is the Falcon 9 from Space-X. Triethylborane can be used as the initiator for polymerizations. Triethylborane-induced polymerizations typically involve free radicals.

## 2.1 Preparation of Trialkylboranes

Triethylborane, also known as triethyl boron, boron triethyl, or triethylborine,  $(\text{C}_2\text{H}_5)_3\text{B}$ ,  $\text{C}_6\text{H}_{15}\text{B}$ , TEB, CAS RN [97-94-9], can be prepared by the reaction of triethylboroxol with triethylaluminum [10, 11]:

This method avoids the use of halogenides. Triethylboroxol can be made from  $\text{B}_2\text{O}_3$  and triethylborane such that 3 moles of triethylborane are ultimately obtained for each mole of triethylborane used as a starting reactant. This can be used as a step in the production of diborane from boron trioxide, assuming that sufficient triethylaluminum is available.

The traditional method of preparing trialkylboranes is the reaction of boron trihalogenides (as etherates) with Grignard reagents:

Triethylborane, tri-*n*-propylborane, and tri-*n*-butylborane were prepared by the reaction of boron trifluoride etherate with alkyl magnesium bromides [12, 13]. Using this method, triethylborane and tri-*n*-propylborane were obtained at purities of 99.8 and 99.7 mol-%, respectively, but the tri-*n*-butylborane was not pure since it decomposed during distillation. The hydroboration of ethylene gives triethylborane [14].

## 2.2 Physical Properties of Trialkylboranes

The physical properties of triethylborane are compiled in Table 1. The boiling point of triethylborane listed in the NIST Chemistry WebBook [15] and accredited to Kostryukov, Samorukov et al. [16], shown as 321.81 K, is incorrect.

**Table 1:** Physical properties of triethylborane.

A similar complete set of physical properties of tri-*n*-propylborane are available in Rosenblum and Allen [12], but they are not included here because this trialkylborane is less likely to be used as a rocket propellant. Its enthalpy of formation is  $-271 \text{ kJ/mol}$  ( $-64.7 \text{ kcal/mol}$ ). The standard enthalpy of formation of liquid trimethylborane (under pressure) is  $-145.6 \text{ kJ/mol}$  ( $-34.8 \text{ kcal/mol}$ ).

The vapor pressure of triethylborane can be calculated from an Antoine equation (shown in the NIST Chemistry WebBook [15] but referenced from very old data):

$$\log p = 2.91408 - [753.261/(T - 112.631)]$$

where  $p$  is the vapor pressure in bar and  $T$  is the temperature in kelvin. Another source gave the vapor pressure as

$$\log p = 7.4856 - 1704.1/T$$

where  $p$  is the vapor pressure in mm Hg and  $T$  is the temperature in kelvin.

### 2.3 Optical Properties of Alkylboranes

The IR spectrum of triethylborane is shown in Figure 1.

**Figure 1:** IR spectrum of triethylborane. (Reproduced and modified with permission from [20].)

A similar IR spectrum of triethylborane is shown in Figure 2 for two different triethylborane concentrations. Tentative assignments of the observed bands in the IR [21] and Raman spectra [22] of triethylborane were made by comparison with the spectra of trimethylborane and ethane.

**Figure 2:** IR spectrum of triethylborane. (Reproduced and modified from [12])

## 2.4 Thermodynamic Properties of Alkylboranes

The heat of combustion is an important property when evaluating any of these compounds for use as fuels for air-breathing jet engines. It is often difficult to obtain accurate data in a calorimeter because the solid combustion products undergo secondary reactions with condensates while the bomb cools down. In many cases it was necessary to extrapolate the enthalpies of formation from other data. Pertinent literature containing thermodynamic data on alkylboranes are summarized in Table 2.

**Table 2:** Literature on the thermodynamic properties of alkylboranes.

An empirical formula for estimating the heat of vaporization of alkylboranes has been derived:

$$(\Delta H)_{\text{evap.}} = 2 + \Sigma(\text{B,C})$$

where  $\Sigma(\text{B,C})$  is the sum of the boron and carbon atoms in the molecule and  $(\Delta H)_{\text{evap.}}$  is the heat of vaporization in kcal/mol. Table 5 gives a comparison of values extrapolated using the above formula with experimentally determined heats of evaporation of boron compounds.

**Table 5:** Comparison of extrapolated and measured heats of evaporation of boron compounds.

| Gross formula                                  | Extrapolated |          | Measured |          |

Data source: [27]

The heats of combustion of trimethylborane (liquid), triethylborane (liquid), and tri-*n*-butylborane (liquid) to form crystalline boric acid, liquid water, and gaseous carbon dioxide were found to be  $2989.4 \pm 22.4$  kJ/mol ( $714.48 \pm 5.36$  kcal/mol),  $4975.6 \pm 15.1$  kJ/mol ( $1189.2 \pm 3.6$  kcal/mol), and  $8901.0 \pm 10.2$  kJ/mol ( $2127.4 \pm 2.4$  kcal/mol), respectively [19]. These data were used along with the heats of formation of boric acid, carbon dioxide, and water to calculate the standard enthalpies of formation of liquid trimethylborane, triethylborane, and tri-*n*-butylborane:  $-145.6 \pm 22.6$ ,  $-197.5 \pm 15.5$ , and  $-348.1 \pm 10.5$  kJ/mol at 298 K, respectively ( $-34.79 \pm 5.40$ ,  $-47.2 \pm 3.7$  and  $-83.2 \pm 2.5$  kcal/mol at 25°C, respectively). See also [16, 29–32].

## 2.5 Molecular Structure of Triethylborane

The molecule of triethylborane is very symmetrical (Figure 3). There is free rotation around the C–C axis in the pendant ethyl groups.

Figure 3: Molecular structure of triethylborane.

## 2.6 Chemical Properties of Alkylboranes

Triethylborane is thermally stable and can be stored indefinitely without undergoing any chemical changes. It ignites spontaneously in air and burns with a green flame. It is not miscible with water and is resistant to hydrolysis, which is a distinct difference from the behavior of triethylaluminum. In chemical commerce, triethylborane is sold as a 11–14-% solution in tetrahydrofuran. Solutions of triethylborane with <14 mass-% in THF are non-pyrophoric in air. Slow exposure to air will oxidize triethylborane solutions to borinic esters and other borate ester materials. Triethylborane does not react readily with atmospheric moisture or water in a THF solution.

### 2.6.1 Thermal Stability of Alkylboranes

A mechanism was proposed for the thermal decomposition of aluminum and boron alkyls and for the reverse reaction, the addition of olefins to metal hydrides [33]. These reactions were shown to be non-radical in nature and they may proceed through a cyclic intermediate.

### 2.6.2 Autoignition of Alkylboranes

Triethylborane is pyrophoric and ignites spontaneously in air or in contact with liquid oxygen and other oxidizers [34, 35].

Triethylborane vapor, at concentrations exceeding 1150–1300 ppm, undergoes complete spontaneous combustion in air to form boron oxide,  $\text{H}_2\text{O}$ , and  $\text{CO}_2$ . At concentrations below 1150 ppm, triethylborane rapidly oxidizes in air to diethylethoxyborane, then ethyldiethoxyborane, and ultimately to triethoxyborane.

The lowest autoignition temperature of cooled triethylborane in air is  $253\text{ K} = -20^\circ\text{C}$ .

For higher molecular mass alkylboranes, the spontaneous ignition delay increases with the length of the alkyl group, so that when liquid tri-*n*-butylborane is exposed to air, there is an induction period of several seconds before ignition occurs.

### 2.6.3 Analysis of Alkylboranes

The number of alkyl groups in alkylboranes can be determined by titration with peroxybenzoic acid. For elementary analysis, the sample is combusted in a CHN analyzer, water and carbon dioxide are absorbed in phosphorus pentoxide and Ascarite, and the boric acid residue is titrated acidimetrically after the addition of mannitol [36]. This method is applicable to all organic boron compounds, even to boric acid esters.

A cartridge that contains a mixture of 15% triethylaluminum and 85% triethylborane, called TEA/TEB, is used as a hypergolic igniter for many LOX/kerosene or LOX/LH2 rocket engines. Quality control of the 15/85 mixture of triethylaluminum and triethylborane is fundamental to ensuring the reliability of engine ignition. Prior to each launch, an infrared spectrophotometric procedure based upon 5 years of studying the correlation between absorbance differences and ignition delay data utilizing the C—C stretching mode at  $10.1\text{--}10.2\text{ }\mu$  for triethylaluminum, and the  $\text{CH}_3$  rocking mode at  $9.7\text{--}9.8\text{ }\mu$  for triethylborane was used for quality assurance [37].

## 2.7 Handling of Alkylboranes

Because most dialkyl and trialkyl boranes, in particular triethylborane, are pyrophoric, they can be handled only under an inert gas (argon, nitrogen) [38]. Argon is preferred because it is heavier than air and it is less likely that air will intrude into the apparatus when the purge gas flow rate is too slow. Transport and storage containers should have two outlets, one for pressurization with an inert gas and the other a dip tube for the withdrawal of liquid.

Alkylboranes with longer alkyl groups are not as reactive in air as triethylborane and autoxidize only slowly without autoignition.

Triethylborane and triethylaluminum have been patented as ignition fluids for solid rocket motors [39].

## 2.8 Toxicity of Trialkylboranes

In earlier investigations, rats were exposed to triethylborane (TEB) via either the i.p., i. g., or inhalation route [40]. The 4-h inhalation LC50 of what was reported to be pure TEB vapor was nominally 700 ppm. However, these data have been considered suspect because the TEB in the exposure environment was not characterized quantita-

tively nor qualitatively and the temporal stability of the exposure concentration was not monitored. Most of it will have been oxidized by the time it was inhaled by the animals.

Clinical symptoms of personnel accidentally exposed to triethylborane indicated that TEB vapors induced both central nervous system and respiratory dysfunction. A renewed investigation was undertaken to re-evaluate the acute inhalation toxicity of TEB in rats exposed for 1 h [41]. It is known that triethylborane is labile in air, undergoing a series of rapid oxidations; thus the toxicity of similar concentrations of TEB vapor (actually TEB oxidation products) was examined at two time points subsequent to the initiation of the spontaneous oxidation process. The acute inhalation toxicity of TEB and its oxidation products was determined not only as a function of concentration but also as a function of time after the initiation of oxidation. Atmospheres with fresh or oxidized TEB at its highest-attainable non-combustive concentration proved to be pneumo- and hepatotoxic as well as lethal. During initial exposure to 900 ppm TEB, 21 of 23 animals expired. The overall LC50 for TEB was 738 ppm.

### 3 Alkyldiboranes

There are mono-, di-, tri-, and tetraalkyldiboranes. In alkyldiborane compounds, some of the hydrogen atoms are bonded to boron and some to carbon. The last two hydrogens of  $B_2H_6$  cannot be replaced because they perform the bridge bonding between the two boron atoms. Alkyldiboranes are pyrophoric in air, similar to trialkylboranes, and can be used for the hypergolic ignition of rocket engines. Alkyldiboranes are more difficult to prepare than trialkylboranes, thus it is less likely that they will be used as rocket propellants.

#### 3.1 Preparation of Alkyldiboranes

Alkyldiboranes can be prepared by the reduction of trialkylboron compounds, by the co-proportionation of a mixture of diborane and trialkylboron compounds, or by the addition of ethylene to diborane. Dialkyldiboranes form symmetrical and unsymmetrical isomers where the two alkyl groups can be on the same boron atom or on different boron atoms.

A mixture of ethyldiboranes were prepared by reacting gaseous diborane and ethylene that were passed through a tube containing a catalyst [42]. The product mixture of mostly *unsym*-diethyldiborane was condensed and recovered in a trap cooled with dry ice, mixed with diborane, and stored at 293–298 K (20–25°C) in a stainless steel container. During storage, a slow reaction occurred in which monoethyldiborane was formed. This product was periodically removed and purified by distillation at low temperatures. When monoethyldiborane was warmed to 298 K

(25°C), a disproportionation reaction took place with the formation of an equilibrium mixture of diborane and *sym*-diethyldiborane, which were easy to separate. The vapor pressure of *sym*-diethyldiborane was 4.8 kPa at 273 K (36 mm Hg at 0°C).

Tetraalkyldiboranes can be obtained by the action of lithium aluminum hydride on the dialkylboron chloride in ether solution [43]:

The alkylation of diborane by reaction with trimethylborane and the decomposition of monomethyldiborane leads to mixtures of alkyldiboranes [44]. See also [45].

### 3.2 Physical Properties of Alkyldiboranes

Table 6 is a summary of the physical properties of some of the more common alkyldiboranes.

The lower heat of combustion of liquid tetraethyldiborane to form steam and solid  $\text{B}_2\text{O}_3$  is  $47865 \pm 293 \text{ kJ/kg} = 11440 \pm 70 \text{ kcal/kg} = 20600 \pm 130 \text{ BTU/lb}$  (corrected for incomplete combustion) [47]. At lower temperatures, boron trioxide and water form boric acid, which changes the overall heat release.

**Table 6:** Physical properties of alkyldiboranes.

<sup>a</sup> Extrapolated

Data source: [46]

Other alkyldiboranes with a gross formula of  $B_2C_4H_8$  were formed by the reaction of diborane with a mixture of acetylene and ethylene. The resulting alkyldiboranes were spontaneously inflammable in air and had a heat of combustion of  $48455 \pm 349 \text{ kJ/kg} = 20850 \pm 150 \text{ BTU/lb}$  [48]. A similar alkyldiborane with a gross formula of  $B_2C_8H_{22}$  was formed by the reaction of diborane with 1,3-butadiene. It reacted rapidly in air, ignited spontaneously in an oxygen-enriched atmosphere, and had a heat of combustion of  $44330 \pm 349 \text{ kJ/kg} = 19075 \pm 150 \text{ BTU/lb}$  [49].

Frequency assignments, including some of the B–C stretching frequencies, were made for the IR spectra of tri-, tetramethyl-, and ethyldiboranes together with some of their boron-deuterated and  $^{10}\text{B}$  isotopic derivatives, and were compared to the Raman spectrum of tetramethyldiborane [50, 51].

For alkyldiboranes, the vibrational frequencies of the terminal B–H bonds lie in the range  $2500\text{--}2600 \text{ cm}^{-1}$  in their IR absorption and Raman spectra, while those of the bridge B–H bonds are in the range  $1500\text{--}1600 \text{ cm}^{-1}$  in their IR spectra.

Vibrational assignments were made, using both IR and Raman data, for the Raman spectra of liquid tetramethyldiborane and 1,1-dimethyldiborane at 203 K ( $-70^\circ\text{C}$ ), and the polarization states of these two alkyldiboranes were investigated qualitatively [52]. The corresponding results were also obtained for monomethyldiborane and trimethyldiborane [53]. Characteristic frequencies of the methyldiboranes showed trends with increasing methyl substitution.

The microwave spectra of ten isotopomers of monomethyldiborane and *unsym*-dimethyldiborane were measured in the region between 18.5 and 40 GHz, and all atom–atom distances and bond angles were derived from these data [54, 55]. The bridge  $B\cdots H_2\cdots B$  group appeared to be displaced toward the methyl group. Thermodynamic properties of several alkyldiboranes are listed in Table 7.

**Table 7:** Enthalpies of formation of alkyldiboranes.

| Compound             | Formula                   | Liquid |          | Vapor  |          |

Data sources: [4,27]

Raman spectra (liquid and solid) and IR spectra (gas and solid) have been measured for samples of *trans*-1,2-dimethyldiborane and *cis*-1,2-dimethyldiborane [56]. Previous spectroscopic work that was originally thought to focus mainly on the *cis* form, is now believed to represent spectra of an equilibrium mixture of both forms.

The molecular geometries, force fields, and IR absorption intensities of diborane and methyldiborane have been predicted from *ab initio* calculations [57]. The theoretical geometries revealed slight distortion of the diborane ring bond angles, by 1–2°, on methylation. The calculated value of the threefold barrier for methyl torsion was nearly 8.5 kJ/mol.

### 3.3 Reactions with Alkyldiboranes

In their chemical properties, the alkyldiboranes are similar to the trialkylboranes; for instance, they autoignite in air at room temperature. However, they are more reactive when they come in contact with water and quickly hydrolyze.

The gas-phase oxidation of *sym*-diethyldiborane has been studied under both explosive and non-explosive conditions [42, 58]. With excess oxygen, the non-explosive reaction was a partial oxidation to form ethyl metaborate and hydrogen. The rate of disappearance of *sym*-diethyldiborane in the slow partial oxidation was found to be zero order in oxygen and first order in *sym*-diethyldiborane. The partial oxidation reaction proceeded via the formation of an unstable intermediate.

Chemical and physical evidence supports the structure  $[(\text{CH}_3)_2\text{B}(\text{NH}_3)_2]^+[\text{H}_2\text{B}(\text{CH}_3)_2]^-$  for the unstable product of the direct reaction of ammonia and tetramethyldiborane [59]. The reaction of ammonia with an ethereal solution of  $(\text{CH}_3)_2\text{BH}_2(\text{CH}_3)_2$  gives the non-electrolyte  $(\text{CH}_3)_2\text{BHNH}_3$ .

## 4 Alkylpentaboranes

Alkylpentaboranes were produced in substantial quantities during the boron fuel program for the XB-70 high-altitude/long-range bomber. HEF-2 consisted of a mixture of alkylpentaboranes, most likely propylpentaborane [60].

Although ethylpentaborane is more easily prepared and purified than ethyldeca-borane, the latter is more attractive as a high-energy fuel for air-breathing engines because of its lower vapor pressure, higher heat of combustion, higher density, better thermal and hydrolytic stability, and the greater ease of handling of decaborane and its derivatives. The combustion of alkylboranes is of most interest in air-breathing engines and not in rocket engines.

## 4.1 History of the Borane Fuels Program

A complete history of the borane fuels program in the United States during the 1950s would fill an entire book and span chapters on all three main boranes (diborane, pentaborane, decaborane) and their alkyl derivatives. The most complete account of the activities during that period is offered in [4]. The following information was extracted from that source. It is included in this discussion of alkylpentaboranes because one of the main ingredients of the HEF fuels was an alkylpentaborane; otherwise, the historical account would have included in the section on alkyldecaboranes. In 1952, the United States Navy (Bureau of Aeronautics) commenced *Project Zip* to develop borane-based fuels with physical properties similar to hydrocarbon jet fuels but substantially higher energies and densities. It was envisaged that such fuels would extend the range, speed, and maximum cruising altitude of existing or planned long-range bombers. Callery Chemical Company and the Olin Mathieson Chemical Corporation were awarded multi-million dollar contracts for the development of these new fuels. Later, in 1957, smaller contracts were given to the Aerojet General Corporation and to AFN, Inc. (a team comprising American Potash and Chemical Corporation, Food Machinery, Inc., and National Distillers). Callery Chemical Company and the Olin Mathieson Chemical Corporation outlined very broad competitive programs for the synthesis of the new high-energy fuels. As the feasibility of the programs proved encouraging, the effort was divided between the United States Navy (*Project Zip* of Callery Chemical Company) and the United States Air Force (*Project HEF*) in 1956. Each of the prime contractors enlisted the help of many subcontractors. Among these subcontractors were industrial research laboratories, research institutes, universities, and private research laboratories. Indeed, during the mid-1950s, the work assumed the character of a crash program similar to the Manhattan Project. It soon became apparent that in order to obtain the desired physical properties, the new fuel would probably need to consist of alkylated derivatives of the boranes. Producing alkylated boranes from borate ores necessitated raising boron from a low-energy oxidized state to a high-energy fuel, and the processes used to achieve this in the two projects were quite different. Olin Mathieson considered the synthesis and demonstration of a usable fuel to be of prime importance; Callery Chemical Company, however, believed that economic feasibility deserved as much emphasis as the synthesis of the fuel. As a result of this divergence in approach, the dissimilarity of the processes became evident. This divergence was particularly evident in the preparation of the earliest alkylated boranes. Olin Mathieson preferred to focus on the preparation of higher boranes, particularly pentaborane(9) and decaborane, and their subsequent alkylation. Callery Chemical Company favored the alkylation of diborane with subsequent pyrolysis to higher alkylated boranes. These process differences make it difficult to compare the chemistry

involved in them. It is regrettable that much of this excellent, original, and creative work was never reported because of the pressures of the times and because it was performed under proprietary or national security restrictions. This small area of boron chemistry was advanced by an unusual amount of research effort in a very short time. When the program was concluded, the attentions of these organized groups of scientists and engineers turned to other tasks, and many lost their jobs. Knowledge of borane chemistry has been markedly advanced by all these efforts, as have associated laboratory techniques and theoretical concepts. The research expenditure on these programs, although large, represented only a small portion of the total cost and was certainly justified by the results. The following sections describe the synthetic routes used by the various chemical companies. The initial steps (lower step numbers), starting from borax ores, have been omitted here; it is assumed that the boron trichloride (trichloroborane) and triethylborate were derived from that source. Lithium hydride and sodium hydride were prepared from the elements.

#### 4.1.1 Olin Mathieson Chemical Corporation Process

**Step (3):** Preparation of diborane from lithium hydride and trichloroborane:

**Step (4):** Formation of pentaborane(9) and decaborane(10) from diborane:

This step was very complex and had not been entirely elucidated. The kinetics and mechanism are described in other sources. The *hot tube* pyrolysis method was used.

**Step (5):** Preparation of propylpentaborane(9) (HEF-2).

Pentaborane(9) was successfully alkylated to propylpentaborane(9) in the presence of ferric chloride as a catalyst. Aluminum chloride could have been used as a catalyst instead, but it could not be separated from the product.

**Step (6):** Preparation of ethyldecaboranes (HEF-3).

Decaborane can be ethylated in the presence of aluminum chloride to yield mono-, di-, and triethyldecaborane:

40–50% conversion was obtained in this process. HEF-3 contained mono-, di-, and triethyldecaborane in the ratio 65 : 30 : 5.

**Step (7):** Preparation of methyldecaboranes.

Mono-, di-, tri-, and tetramethyldecaborane were formed from decaborane and methyl chloride in the presence of aluminum chloride. The mass ratio of these materials in the order given was 67 : 24 : 7 : 2.

**4.1.2 Callery Chemical Company**

A different approach to the synthesis of alkylboranes was taken at Callery Chemical Company.

**Step (4):** Preparation of dimethoxyborane:**Step (5):** Preparation of diborane.

The disproportionation of dimethoxyborane to diborane proceeded readily with nearly 100% conversion. The disproportionation was favored by increased pressure and temperature.

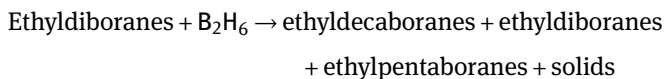

**Step (6):** Preparation of ethyldiboranes.

When allowed to react at 308 K (35 °C) and 69 kPa gauge (10 psig), diborane and ethylene yielded a mixture of ethyldiboranes. This reaction was 95% complete with respect to diborane and complete with respect to ethylene. Between 2 and 3 moles of ethylene were used per mole of diborane.

**Step (7):** Preparation of crude ethyldecaboranes (HiCal-2).

Additional diborane was added to mixed ethyldiboranes at 343 K (70 °C) and 2.76 MPa gauge (400 psig) to yield a mixture of ethyldecaboranes and ethylpentaboranes. The excess ethyldiboranes were removed by distillation, and the resulting product was HiCal-2.

**Step (8):** Preparation of refined ethyldecaboranes (HiCal-3).

Dissolved solids were removed by precipitating and diluting with 20 volumes of pentane and filtering. The pentane was removed by stripping with an inert gas to yield HiCal-3.

**Step (9):** Preparation of methyldecaboranes (HiCal-4).

Diborane from Step (5) was pyrolyzed to decaborane and other boranes and the decaborane was methylated over an aluminum chloride catalyst with a reported yield of 60–85% methyldecaboranes. A mixture of mono-, di-, tri-, and tetramethyldecaboranes was reported, but the composition was not given.

Other methods were tested at Stauffer-Aerojet Chemical Company and at a team called AFN, Inc. (a team of chemical companies formed by American Potash and Chemical Corporation, Food Machinery, Inc., and National Distillers), but they did not advance beyond the pilot plant scale. The final fuel objectives at AFN, Inc. were the preparation of HEF-4 or pentaborane(9).

## 4.2 Production of Alkylpentaboranes

Alkylpentaboranes can be prepared by the addition of alkenes to pentaborane or by the pyrolysis of diborane in the presence of trialkylboron compounds. The reaction of diborane with trimethylborane at 508–573 K (235–300 °C) leads to the formation of about 5% methylpentaborane in addition to pentaborane as the main product [61]. The mixture contains two isomers of methylpentaborane that can be separated by low-temperature fractionation. The less volatile isomer has a vapor pressure of 2.7 kPa (20 mm Hg) at 273 K (0 °C).

Several reactions of pentaborane(9) that lead to alkylpentaboranes have already been discussed in the section on the reactions of pentaborane with organic compounds. The addition of alkenes to pentaborane is catalyzed by amines (e.g., trimethylamine, pyridine) [62, 63]. Isobutylpentaborane, which has a vapor pressure of 0.67 kPa at 298 K (5 mm Hg at 25 °C), can be made by reacting pentaborane(9) with isobutylene [64]. The use of tetrahydrofuran as a solvent improves the alkylpentaborane yield [65].

Reactions involving alkene addition to pentaborane can be catalyzed by Friedel–Crafts catalysts such as  $\text{AlCl}_3$  [66]. The ethyl group in ethylpentaborane is located preferentially in the apex (apical position), i.e., the ethyl group is attached to the boron atom of the pentaborane molecule, which is not in the plane of the base of the pyramid in which the boron atoms are located. Ethylpentaborane can be prepared by reacting ethylene with pentaborane in the presence of a Friedel–Crafts catalyst, e.g., anhydrous aluminum chloride. The reaction takes place in a nickel–chromium alloy vessel at a pressure in excess of 354 kPa (3.5 atm) and a temperature of 318–333 K (45–60 °C).

The addition of propylene to pentaborane(9) at 433–468 K (160–195 °C) can be catalyzed by magnesium silicate catalysts [67].

Another production method for alkylpentaboranes is the alkylation of pentaborane by alkyl halogenides in the presence of Friedel–Crafts catalysts [68, 69]. The reaction of 2*B*-methylpentaborane with chloromethane in the presence of  $\text{AlCl}_3$  leads to the formation of 1,2-dimethylpentaborane. Alkylpentaboranes often undergo intramolecular rearrangements.

The reaction of pentaborane and ethylene oxide resulted in a viscous yellow liquid that was not pyrophoric in air [70].

The reaction of methyl chloride with pentaborane in the presence of  $\text{AlCl}_3$  at 373 K for 3 h gives a good yield of 1*B*-methylpentaborane. If 1*B*-methylpentaborane is heated to 473 K (200 °C) overnight, it rearranges itself to form 2*B*-methylpentaborane [71]. The rate of apex-to-base rearrangement is retarded if the number of substituents is increased [72].

Butylpentaborane and tributylborane were prepared from pentaborane(9) and isobutylene [73]. Mono-*sec*-butylpentaborane(9) has a vapor pressure of 0.5 kPa at

298 K (4 mm Hg at 25 °C), and monopropylpentaborane(9) has a vapor pressure of 0.9 kPa at 293 K (7 mm Hg at 20 °C).

It is possible to synthesize alkylpentaboranes with two pentaborane entities in the molecule that are connected by an alkane chain. 1,4-Dipentaboranylbutane can be obtained by the reaction of butadiene with pentaborane [74, 75].

The preparation of dipentaborylmethane by reacting pentaborane with dichloromethane in the presence of aluminum chloride gave poor yields of less than 1% [76]. No dipentaborylethane resulted from the reaction of pentaborane with 1,2-dichloroethane or 1,2-dibromoethane. Instead, these reactions produced ethylpentaborane in yields of up to 47%.

The complex product obtained by reacting ethylene with diborane has been shown by vapor-phase chromatography to include, among others, two homologous series, namely ethylpentaboranes(9) and ethyldecaboranes(11). At 673 K (400 °C), diborane and ethylene predominantly produce triethylborane. However, when heated, diborane decomposes to give higher boron hydrides, and while triethylborane is an alkylating agent, borane and ethylene might be expected to give ethyl derivatives of the higher boron hydrides under suitable conditions [77, 78].

Aluminum-chloride-catalyzed Friedel–Crafts reactions have generally been used to prepare alkylpentaboranes and alkyldecaboranes, although several methyl derivatives were obtained by simultaneous pyrolysis and alkylation using trimethylboron. It was possible to isolate two isomeric monomethyl pentaboranes. One of the isomers, which had a vapor pressure of 4.67 kPa at 273 K (35 mm Hg at 0 °C), was identical to the apically substituted product obtained by Friedel–Crafts methylation of pentaborane. Propyl pentaborane is the major constituent (70–85%) of boron fuel, HEF-2. The material also contains dipropylpentaborane (15–25%) and pentaborane (3–5%).

A slurry of  $\text{AlCl}_3$  in pentaborane rapidly absorbs ethylene gas, forming monoethylpentaborane(9) [79].

### 4.3 Physical Properties of Alkylpentaboranes

The physical properties of ethylpentaborane(9) are listed in Table 8.

Methylpentaborane freezes at 216 K (–57 °C) and boils at 348 K (75 °C). 1,4-Dipentaboranylbutane has a boiling point of 333–353 K at 267–67 Pa (60–80 °C at 2–0.5 mm Hg) [74]. The heats of combustion of alkylpentaboranes and alkyldecaboranes are listed in Table 9. Table 10 gives a comparison of the physical properties of alkylpentaboranes and alkyldecaboranes. Thermodynamic properties of alkylpentaboranes are listed in Table 11.

**Table 8:** Physical properties of ethylpentaborane.

| Property            | SI units                   | Other units              | References |

Data sources: [4,27]

Ethyldecaborane is more stable than ethylpentaborane with respect to hydrolysis and thermal decomposition. The molecular structure of ethylpentaborane is similar to that of bromopentaborane [81]. From analyzing the infrared spectrum of pentaborane, the ethyl group in ethylpentaborane was found to be located at the apical position of the pentaborane molecule (Figure 4) [82]. The infrared spectra of pentaborane, bromopentaborane, methylpentaborane, and ethylpentaborane in the ranges 1900–400 and 3000–2500  $\text{cm}^{-1}$  were measured and compared. The spectra of methylpentaborane and ethylpentaborane were observed to be very similar. The structure of *n*-propylpentaborane (HEF-2) would be similar to that of ethylpentaborane.

**Figure 4:** Molecular structure of ethylpentaborane

The apex-basal dimethylpentaborane 1,2-( $\text{CH}_3$ )<sub>2</sub>B<sub>5</sub>H<sub>7</sub> was shown by XRD to rearrange itself into the dibasal isomer 2,3-( $\text{CH}_3$ )<sub>2</sub>B<sub>5</sub>H<sub>7</sub>, in which the methyl groups are on adjacent basal B atoms of the square-pyramidal B<sub>5</sub> unit [83]. The space group of crystalline 2,3-dimethylpentaborane is *Pm* $\bar{c}$ *n*, and there are four molecules in the unit cell. The unit cell parameters are:  $a = 12.55 \text{ \AA}$ ,  $b = 6.39 \text{ \AA}$ , and  $c = 9.10 \text{ \AA}$ .

#### 4.4 Reactions of Alkylpentaboranes

The thermal decomposition of ethylpentaborane at 458–517 K (185–244 °C) leads to non-volatile polymers, hydrogen, methane, and traces of decaborane [84]. The thermal decomposition of ethylpentaborane at temperatures of 458–517 K (185–244 °C) has a reaction order of approximately 1.5. Ethylpentaborane has a greater rate of decomposition than pentaborane itself [85].

1-Alkylpentaboranes rearrange themselves into 2-alkylpentaboranes when heated to 473 K (200 °C) [71]. This can be a deliberate, pre-planned step in the synthesis of 2-alkylpentaboranes from pentaborane.

The products of the decomposition of propylpentaborane (HEF-2) in the range 420–463 K (147 to 190 °C) were hydrogen, hydrocarbons, and a solid, non-volatile, yellow boron hydride [86]. The following equation that may be used to calculate the ap-

proximate time required to decompose 20% of propyl pentaborane as a function of temperature was developed:

$$\log(t_{20} - 2) = 7.85 \times \frac{10^3}{T} - 16.3$$

where  $t_{20}$  is the time required for 20% decomposition in minutes and  $T$  is the temperature in kelvin.

#### 4.5 Toxicity of Alkylpentaboranes

Alkylpentaboranes are somewhat less toxic than pentaborane itself. The toxicity hazards of HEF-2 necessitated extensive precautions during the handling of these exotic jet engine fuels and ultimately contributed to the termination of the boron fuels program [87, 88].

Acute and subacute studies on HEF have established a linear relationship between serum borane levels and clinical signs of toxicity [89]. Repeated exposure to low levels resulted in tissue accumulation and the appearance of toxic effects as a function of time and dose. The accumulation of HEF in tissues limited the usefulness of the biological index test procedure as a diagnostic aid in cases of chronic human exposure during work hours.

### 5 Alkyldecaboranes

Alkyldecaboranes were the mainstay of the boron high-energy fuels (HEF) program. While HEF-2 consisted of propylpentaborane, HEF-3 was a mixture of ethyldecaboranes. HEF-5 may have consisted of a butyldecaborane. Hi-Cal was a mixture of two components.

HEF-3, a boron fuel that was once commercially available in the US, consisted of decaborane (6.8%), monoethyldecaborane (69.4%), diethyldecaborane (22.4%), and triethyldecaborane (1.4%). Another boron fuel from a commercial source in the US, HiCal-3, was prepared by the simultaneous ethylation and pyrolysis of diborane and ethylene and contained mono- and polyethylated decaborane as well as the corresponding derivatives of pentaborane.

#### 5.1 Production of Alkyldecaboranes

Both Olin Mathieson and Callery Chemical Company constructed large facilities for the synthesis of alkylboranes on an industrial scale. Olin Mathieson built a facility at Niagara Falls, NY and Callery built a facility near Muskogee, OK. They also built an ad-

jacent facility for producing ethylene that was needed to alkylate the boranes. Callery later became a division of Mine Safety Appliances Company and then a subsidiary of Ascensus.

Alkyldecaboranes can be prepared by the reaction of decaborane with alkyl halogenides and anhydrous aluminum chloride [90], by the pyrolysis of diborane and trialkylborane or alkylidiboranes at 373–773 K (100–500 °C) in a reactor with a short dwell time [91], from decaborane and ethylene [92], from decaborane with Grignard compounds [93], from decaborane and metal-organic compounds, e.g., ethyl lithium [94], from diborane and alkylidiborane in an autoclave at high pressure and high temperature [95], or by high-pressure reaction of diborane and ethylene [96]. The reaction of diborane with ethylene can proceed explosively at high pressure. See also [77, 78].

## 5.2 Physical Properties of Alkyldecaboranes

Monoethyldecaborane boils at 368–388 K (97–115 °C) at a reduced pressure of 466 Pa (3.5 mm Hg). HiCal-2 is a mixture of several alkyldecaboranes. As summarized in Table 12, an elemental chemical analysis of HiCal-2 was performed, and its heat of combustion, vapor pressure, decomposition, freezing point, density, self-ignition temperature, flash point, and blow-out velocity were determined [97]. When conducting blowout velocity tests with this fuel, considerable difficulties were encountered

**Table 12:** Properties of HiCal-2.

| Property                                                                                                      | SI units                                                         | Other units                                                          |

Data source: [97]

because of foreign matter in the fuel. Filters in the transfer lines became clogged with a solid and gelatinous material.

Table 13 is a summary of the physical properties of ethyldecaborane and diethyldecaborane. The original source has additional data for a wider temperature range of 273–333 K (0–60 °C).

Thermodynamic properties of alkyldecaboranes are listed in Table 14.

**Table 13:** Physical properties of 1-ethyldecaborane and 1,2-diethyldecaborane.

### 5.3 Chemical Properties of Alkyldecaboranes

#### 5.3.1 Ignition of Alkyldecaboranes

Alkyldecaboranes autoxidize readily in contact with air. A mixture of 4% decaborane, 61% ethyldecaborane, 29% diethyldecaborane, and 6% triethyldecaborane autoignites in air at 403 K (133 °C). Autoignition may be an undesirable hazard. The autoignition temperature can be increased (i.e., the mixture can be made safer to handle) by the addition of trace iodine [99].

#### 5.3.2 Thermal Decomposition of Alkyldecaboranes

The kinetics of the thermal decomposition of 2-ethyldecaborane in a static system in the temperature range 483–503 K (210–230 °C) and at 2-ethyldecaborane pressures of 13.3–80 kPa (100–600 mm Hg) were examined [100]. The rate of decomposition, which initially leads to decaborane and diethyldecaboranes, is second order with respect to 2-ethyldecaborane. The activation energy was  $165 \pm 2$  kJ/mol ( $39.5 \pm 0.5$  kcal/mol). In the later stages of the decomposition, the reaction deviates from a second-order dependence due to side reactions that give non-volatile solid hydrides, alkylated non-volatile solid hydrides, hydrogen, methane, and a little ethane. 1,2-diethyldecaborane was always present in the products in greater concentrations than 2,4-diethyldecaborane.

The thermal stabilities of a commercial grade of ethyl decaborane (HEF-3) and of decaborane were investigated at temperatures of 475 and 525 K (202 and 252 °C) [101]. The decomposition products were hydrogen and a boron hydride, which was a solid or viscous liquid. Ethyl decaborane also yielded methane and/or ethane. For HEF-3, the following equation that allows the time required to decompose 20% of the ethyl decaborane at any other temperature to be calculated was developed:

$$\log(t_{20\%} - 2) = 7.12 \times \frac{10^3}{T} - 13.3$$

where  $T$  is the temperature in kelvin and  $t$  is the decomposition time of 20% of HEF-3 in minutes.

#### 5.3.3 Analysis of Alkyldecaboranes

Many of the HEF fuels were mixtures or contained contaminants that needed to be analyzed. HiCal-3 was expected to contain unreacted pentaborane as a contaminant. A combination GC/IR method was developed that was capable of detecting small amounts of pentaborane in HiCal-3 [102].

The boron contents of alkyldecaboranes and similar non-volatile boron compounds can be determined by oxidizing the sample with alkaline potassium persulfate and performing a potentiometric titration of the boric acid formed, with the acidity enhanced by the addition of mannitol [103].

### 5.4 Handling of Alkyldecaboranes

All alkylboranes, whether they are alkylpentaboranes or alkyldecaboranes, must be handled with extreme care [104]. The hazards of HEF-2 are similar to those of pentaborane itself. Spilled HEF-2 may autoignite at any moment. Spilled HEF-2 should first be diluted with a high-boiling kerosene and then flushed with a dilute aqueous ammonia solution. HEF-3 and HEF-4 do not autoignite as readily as HEF-2. The main hazard during the handling of HEF-3 or HEF-4 is accidental contact with the skin and resorption through it, resulting in severe chronic poisoning.

### 5.5 Toxicity of Alkyldecaboranes

The LD50 of boron fuels of the HEF-3 or Hi-Cal type in rats is 13 mg/kg for intravenous (*i.v.*) injection and 317–500 mg/kg for slow resorption through the skin. The LC50 for a 4-h inhalation period is 23 ppm.

The recommended first-aid treatment for splashes of HEF fuels on the skin is flushing of the affected area with a 2.8% aqueous ammonia solution or with a triethanolamine solution.

See also [105, 106] for brain and central nervous system effects of borane fuels.

Applying 0.1–0.012 cm<sup>3</sup> of HEF-3 daily to the skin of rats proved fatal after several days [107]. When symptoms were severe, the doses were adjusted downward to maintain severe intoxication, and daily exposure continued for 2 or 4 weeks in order to study its effects on the central nervous system. Intoxication developed in three stages: (1) hyperexcitation with coordinated movements or twitching and aggressive behavior after a few hours; (2) depression interrupted by agitation accompanied by ataxia; and finally (3) coma. The first two stages were reversible. Convulsions occurred only after massive lethal doses. Repeated subliminal doses produced sudden intoxication after several symptom-free days. Nuclei of nerve cells were enlarged and neurons with reduced chromatin or a disorganized chromatin pattern seemed more frequent.

## 6 Other Boron-Containing Organic Compounds

Boron, either in the elemental state or in boron hydrides or boron-organic compounds, is a preferred fuel ingredient for rocket propellants because of its light weight and high heat of combustion, mainly due to the highly negative enthalpy of formation of the boron trioxide (B<sub>2</sub>O<sub>3</sub>) that forms as a combustion product.

## 7 Boron-Containing Polymers

Low molecular weight alkylboranes are liquids or even gases, but higher molecular weight alkylboranes and polyalkylboranes are solids that can be formulated into solid propellants. Boron-containing polymers can serve as binders and at the same time increase the heats of combustion and the specific impulses of solid propellants as compared to solid propellants formulated with polymeric hydrocarbon binders. The use of boron-organic compounds as binders will also increase the burning rates of those propellants compared to the burning rates of baseline hydrocarbon-bonded propellants.

Polymeric (BNH) compounds form upon the thermolysis and dehydrogenations of ammonia borane or borine hydrazine [108], but they are brittle and have no strength. One intermediate,  $\text{H}_2\text{BNHNHBH}_2$ , exists mostly in a polymeric form.

## 8 Carboranes

The discovery of the icosahedral *closo*-1,2-dicarbadoecaborane(12),  $1,2\text{-C}_2\text{B}_{10}\text{H}_{12}$ , led to the rapid development of carborane chemistry [109]. The discovery of the base-promoted degradation of isomeric *closo*- $\text{C}_2\text{B}_{10}\text{H}_{12}$  cages provided one of the most important carborane anion systems, isomeric [*nido*- $\text{C}_2\text{B}_9\text{H}_{12}$ ]<sup>−</sup> anions. Carboranes have been extensively tested as burning-rate-accelerating additives in solid propellants. Many dicarbaboranes exist as isomers that differ in the relative locations of the carbon centers. The boron atoms and the associated hydrogen atoms are not identified in the schematic of a carborane molecule shown in Figure 5.

Figure 5: Structure of *ortho*-carborane.

*n*-Hexylcarborane, CAS RN [20740-05-0], is a burning rate catalyst for solid propellants. There were very ambitious projects to scale up the production of *n*-hexylcarborane to 13 metric tons per year [110]. A production facility like this would consume a substantial amount of diborane to make decaborane as an intermediate. The decaborane would then be reacted with 1-octyne to make *n*-hexylcarborane. The plan was to construct the plant next to an existing diborane production facility. The

principal hazards identified were the toxicity of borane and the fire hazard due to flammable materials and solvents.

The relative toxicities of technical grade *n*-hexylcarborane (NHC), carboranyl-methylethyl sulfide, and carboranylmethylpropyl sulfide were investigated using rats, guinea pigs, rabbits, and dogs [111]. Each compound produced primary irritation when applied to the intact and abraded skin of rabbits. Data indicated only a minor toxic hazard would be expected from acute accidental ingestion. Acute vapor and aerosol inhalation exposures of animals to the three compounds resulted in no deleterious effect. Respiratory irritation with some minimal lung damage and transient eye effects occurred in dogs and rats as a result of repeated exposure to aerosols of NHC for 6 h/d, 5 d/week for 6 weeks at concentrations of 77 and 245 mg/m<sup>3</sup>.

Carborane-4,1,6-C<sub>2</sub>B<sub>4</sub>H<sub>6</sub>, is pyrophoric in air, similar to pentaborane, and reacts violently with water. Carboranes may be suitable as additives to conventional fuels to ease their ignition and widen the range of operating pressures, allowing jet aircraft to fly at higher altitudes. The ignition delay of air/carborane mixtures is shorter than that of air/H<sub>2</sub> or air/hydrocarbon mixtures by one and three orders of magnitude, respectively [112]. The limiting ignition stage is the pyrolysis of carborane. The carborane-6 molecule has an octahedral structure whose apexes are occupied by boron and carbon atoms. A structure of this type presumes a high degree of electron localization in the boron-carbon skeleton. Therefore, carborane-4, like the higher carboranes, is a quasi-aromatic system. There are two isomers: 1,6- and 1,2-C<sub>2</sub>B<sub>4</sub>H<sub>6</sub>. The combustion of carborane-4 proceeds in accordance with the following equation:

The ignition delay of carborane-4/oxygen/argon mixtures behind reflected waves in a shock tube at 700–1600 K and 0.05–0.15 MPa was measured experimentally, and the kinetics of the initial stage of carborane oxidation were derived from these data [113]. The initial products of carborane oxidation were predicted from a semiempirical MNDO quantum-chemical method. A kinetic scheme for the promoted ignition of stoichiometric oxygen/carborane-4/argon mixtures in the presence of isopropyl nitrate (to promote additions) at a temperature of 600–1300 K and under a pressure of 0.1 ± 0.02 MPa was derived and compared to experimental results [114].

The heats of combustion, formation, and sublimation of *o*- and *m*-carboranes were determined calorimetrically, and it was confirmed that *o*-carborane is less thermodynamically stable than *m*-carborane [115].

## 9 Other Boron Compounds

Adducts between borane and trinitromethyl anions have been characterized and could be used as rocket propellants [116].

# Alkylhydrazines

## Introduction

There are three chapters relating to alkylhydrazines in *Encyclopedia of Liquid Fuels*, with the titles “Alkylhydrazines” (the chapter at hand), “Dimethylhydrazines,” and “Methylhydrazine.” The current chapter deals with alkylhydrazines in general and alkylhydrazines other than methylhydrazine (MMH), unsymmetrical dimethylhydrazine (UDMH), or symmetrical dimethylhydrazine (SDMH). It also contains a short section on arylhydrazines. All alkylhydrazines are potentially valuable rocket propellant fuels. Alkylhydrazines can contain one to four alkyl groups attached to the hydrazine molecule, replacing one or more hydrogens in  $N_2H_4$  with an alkyl group. For dialkylhydrazines, the two alkyl groups can be attached to either the same nitrogen atom (unsymmetrical dialkylhydrazines, *N,N*-dialkylhydrazines, 1,1-dialkylhydrazines) or to different nitrogen atoms (symmetrical dialkylhydrazines, *N,N'*-dialkylhydrazines, 1,2-dialkylhydrazines). Alkylhydrazines have been called hydrazinoalkanes, but that is an antiquated nomenclature, just like the name “diamine” should no longer be used for hydrazine. The properties of the parent compound, hydrazine, are summarized in the chapter “Hydrazine” of the *Encyclopedia of Liquid Fuels*.

## 1 Alkylhydrazines

The primary objective of this chapter on alkylhydrazines is to summarize the physical and chemical properties and uses of organic hydrazine-derivative fuels. It also includes the higher and substituted alkylhydrazines that do not belong in either of the chapters on mono- or dimethylhydrazines. A book many times the size of the current book volume would have to be written if all organic hydrazine derivatives had to be included. However, this is not necessary because some excellent summaries of organic hydrazine derivatives have already been published, and because only a selected few are used as rocket fuels. The second edition of the book *Hydrazine and Its Derivatives* contains detailed information on all alkylhydrazines, including those of interest as rocket propellants. Other sources (some more historical) of information on alkylhydrazines can be found in [1–12].

Our discussion of organic hydrazine derivatives and their preparation in this chapter is thus restricted to alkylhydrazines that have been considered or have actually been used as rocket propellants. Many other hydrazine derivatives have found applications as herbicides or pharmaceuticals or plastic processing ingredients, and in some instances have benefited from the ready availability of hydrazines that were initially prepared as a result of the missile and space programs. There are many

**Table 1:** Physical properties of methylhydrazines in comparison to hydrazine.

| Property                              | Unit                                                 | N <sub>2</sub> H <sub>4</sub> | MMH                     | UDMH                    | SDMH                    |

Note: All listed property values (except for the heat of vaporization) were obtained at 298 K (25 °C)

methods for the production of alkylhydrazines [13], but only a few of those have actually advanced to the level of industrial-scale production.

### 1.1 Physical Properties of Alkylhydrazines

Table 1 gives a juxtaposition of physical properties of several alkylhydrazines with those of their parent compound, anhydrous hydrazine,  $\text{N}_2\text{H}_4$ . Additional physical properties are listed in individual tables in the following sections on specific alkylhydrazines.

### 1.2 Molecular Structure of Alkylhydrazines

The  $^{14}\text{N}$  nuclear quadrupole resonance spectra at 77 K of several hydrazines were analyzed in the framework of a semi-empirical theory that was extended to cover the case of large asymmetry parameters for the molecules [14]. The atomic-orbital occupation numbers obtained by this analysis were linked with the hydrogen-bonding configuration in the solid state. The results indicated that the hydrogen-bonding ability of the amino nitrogen exceeds that of the substituted nitrogen atom and decreases in the order: hydrazine > alkyl hydrazines > *N*-amino heterocycles > aryl hydrazines. See also [15, 16].

### 1.3 Thermal Stability of Alkylhydrazines

Replacing one or more hydrogens on hydrazine with alkyl groups can improve the thermal stability of this molecule. Some of the cyclic hydrazines have remarkable thermal stability. In most instances, the thermolysis of hydrazine compounds starts with the breaking of the N—N bond.

### 1.4 Toxicity of Alkylhydrazines

Some alkylhydrazines, predominantly 1,2-dimethylhydrazine, symmetrical dimethylhydrazine, SDMH, are distinctly carcinogenic, but not all alkylhydrazines are in the same hazard category [17]. For UDMH, the hazard is higher for its autoxidation product, *N*-nitrosodimethylamine,  $(\text{CH}_3)_2\text{NNO}$ , NDMA, than for the pure alkylhydrazine from which it is derived. In many instances, NDMA was present in UDMH of poor quality, and the toxicity reported in the literature may have been caused by the NDMA contaminant, and not by UDMH itself. Many of the early toxicity studies used UDMH of

inferior quality, UDMH made from NDMA, or they deliberately used the same poor-quality stuff that the soldiers might be exposed to at the missile launch sites.

Alkylhydrazines such as methylhydrazine derivatives occur naturally in mushroom poisons such as gyromitrin [18]. A phenylhydrazine derivative, agaritine, occurs naturally in the commonly eaten brown cap mushrooms.

## 2 Methylhydrazine

See the separate chapter on methylhydrazine in *Encyclopedia of Liquid Fuels*.

## 3 Dimethylhydrazines

See the separate chapter on dimethylhydrazines in *Encyclopedia of Liquid Fuels*.

## 4 Trimethylhydrazine

Trimethylhydrazine and tetramethylhydrazine have not been used as rocket propellants. They may be encountered as contaminants in UDMH that was prepared by direct methylation of hydrazine. In the search for less toxic replacements for UDMH, trimethylhydrazine and tetramethylhydrazine were good candidates due to their lower vapor pressure and reduced tendency to form nitrosoamines, but no efforts have been made to produce and test them on a larger scale. Trimethylhydrazine or tetramethylhydrazine may be less toxic than UDMH. When looking for methods for the disposal of surplus UDMH by conversion to a useful product, the methylation of UDMH to make trimethylhydrazine or tetramethylhydrazine may be an option if new applications for trimethylhydrazine or tetramethylhydrazine can be found.

### 4.1 Preparation of Trimethylhydrazine

Trimethylhydrazine can be obtained in 63.8% yield by reduction of 1,1-dimethyl-2-formylhydrazine with lithium aluminum hydride [19], which is prepared from UDMH and methyl formate:

Continuation of this methylating reaction using trimethylhydrazine instead of UDMH as a starting material leads to tetramethylhydrazine.

Trimethylhydrazine and tetramethylhydrazine were first prepared in 1952 [20, 21]. These compounds were not accessible by direct methylation of hydrazine with dimethyl sulfate. Instead, trimethylhydrazine was prepared by reduction of formaldehyde 1,1-dimethylhydrazone (methylene-dimethylhydrazine) with lithium aluminum hydride:

Trimethylhydrazine can be prepared in two steps from UDMH, using an easy-to-scale-up procedure that avoided difficult acid–base extractions [22]. The procedure provided trimethylhydrazine as a solution in 1,4-dioxane.

## 4.2 Physical Properties of Trimethylhydrazine and Tetramethylhydrazine

For the sake of saving space, the physical properties of trimethylhydrazine and tetramethylhydrazine have been combined here in one place, Table 2. The properties are quite different from those of MMH or UDMH, illustrating the effect of progressive methylation on the physical properties of the hydrazine ( $\text{H}_2\text{NNH}_2$ ) molecule.

The IR and Raman spectra of liquid and gaseous trimethylhydrazine have been measured, and can be used to check for the presence of trimethylhydrazine as an impurity in UDMH [28]. The vapor-phase spectra of trimethylhydrazine reported there were later shown to be mostly those of oxidation products such as methylene dimethylhydrazine (formaldehyde dimethylhydrazone) [29]. The later study used a 10-cm cell and scanned spectra from 2 to 15  $\mu\text{m}$ . Their liquid trimethylhydrazine spectra agreed with those reported by Shull et al., but the vapor spectra were quite different.

### 4.2.1 Molecular Structure of Trimethylhydrazine

Trimethylhydrazine can exist as stereoisomers: *cis*-trimethylhydrazine and *trans*-trimethylhydrazine. Using *ab initio* calculations of the trimethylhydrazine molecule, it was shown that the *anti* and *syn* conformers occupy energy maxima when the molecule is rotating around the N–N bond [30].

## 4.3 Chemical Properties of Trimethylhydrazine

The autoxidation of trimethylhydrazine leads to formaldehyde dimethylhydrazone [29]. Trimethylhydrazine can be identified by its mass spectrum [31]. Trimethylhydrazinium nitrate, perchlorate, dinitramide, azide, nitroformate, and 5-aminotetrazolate have been characterized as energetic materials [32].

**Table 2:** Physical properties of trimethylhydrazine and tetramethylhydrazine.

#### 4.4 Toxicity of Trimethylhydrazine

The reason for studying the toxicities of trimethylhydrazine and tetramethylhydrazine was to see if reducing the number of reactive N—H bonds in hydrazines would also reduce their toxicity. Giving 0.05% trimethylhydrazine hydrochloride solution to Swiss mice with their drinking water throughout their lives increased the incidence of blood vessel tumors from 5 (control group) to 85, lung tumors from 22 to 44, and kidney tumors from 0 to 6 [33, 34]. Histopathologically, tumors were classified as angiosarcomas of blood vessels and adenomas of the lungs and kidneys. Similar results were obtained with trimethylhydrazine in Syrian golden hamsters [35].

## 5 Tetramethylhydrazine

Tetramethylhydrazine is not likely to be used as a rocket propellant. It is more difficult to prepare than UDMH. Tetramethylhydrazine may be a contaminant in UDMH that was prepared by direct methylation of hydrazine or MMH. Tetramethylhydrazine may be less toxic than UDMH.

### 5.1 Preparation of Tetramethylhydrazine

The first preparation of tetramethylhydrazine started with hydrazine, and involved converting it to the 1,2-diformylhydrazine by reaction with sodium formate, methylating the two free NH groups with dimethyl sulfate, and reducing the formyl groups with lithium aluminum hydride [21]:

The yield in this lengthy process was only very low (15%). Other investigators followed a different route by using methyl formate instead of sodium formate and again reducing the formyl compound with lithium aluminum hydride [19]. The yield was 55% in the last step and 63.5% in the first step, resulting in an overall yield of 35%. Tetramethylhydrazine and methyl iodide or bromide form crystalline pentamethylhydrazonium salts. The mechanism of the reaction of trimethylhydrazine with formic acid and subsequent reduction with formaldehyde under the evolution of carbon dioxide is not quite clear, but the product is tetramethylhydrazine, which can be distilled from the mixture of reaction products as an azeotrope with water [36]. Very good yields (35% based on hydrazine as a starting material) can be obtained by reacting hydrazine hydrate with chloroformic acid ethyl ester, methylating with dimethyl sulfate, and reducing with lithium aluminum hydride [37]:

Eleven different tetraalkylhydrazines, most of them including heterocyclic rings, have been prepared by using cyanoborohydride in place of lithium aluminum hydride as a reducing agent [38]. The yield ranged from 27 to 59%.

Tetramethylhydrazine was first prepared in 1952 [20, 21]. This compound was not accessible by direct methylation of hydrazine with dimethyl sulfate.

Tetramethyltetrazene, readily prepared by oxidation of UDMH (see *Encyclopedia of Liquid Fuels*, chapter Dimethylhydrazines), will split off molecular nitrogen by photolytic decomposition under UV light, resulting in the formation of tetramethylhydrazine [39, 40].

Hydrazine hydrate and formamide were used as starting materials to form *N,N'*-diformylhydrazine and then reacted with dimethyl sulfate to make *N,N'*-dimethyl-*N,N'*-diformylhydrazine by methylation. Finally, reduction by lithium aluminum hydride yielded tetramethylhydrazine in an overall yield of 15% [41].

## 5.2 Physical Properties of Tetramethylhydrazine

Physical properties of tetramethylhydrazine are included in Table 2 above. The IR spectra of trimethylhydrazine and tetramethylhydrazine are included in a catalog of IR spectra for the qualitative analysis of gases [42]. This useful summary also includes IR spectra of 30 other compounds found in propellant mixtures. Tetramethylhydrazine showed absorption bands at the following wavenumbers (in  $\text{cm}^{-1}$ ) [25]: 3000(vs), 2960(vs), 2830(vs), 2780(vs), 1450(vs), 1231(vs), 1201(w), 1151(vs), 1089(s), 1026(vs), 969(w), 712(s), 508(s), and 435(w). An extended scan of spectra of gaseous and solid tetramethylhydrazine in the far IR in comparison to Raman spectra provided some insight into the molecular structure of tetramethylhydrazine [43]. Most of the fundamental vibrations could be assigned to specific bonds and atom groups in the molecules. Tetramethylhydrazine exists in the *gauche* conformation and has  $C_2$  symmetry in all phases. Like hydrazine itself, tetramethylhydrazine also exists preferentially in the *gauche* form and has  $C_2$  symmetry in all phases.

The IR spectrum of gaseous tetramethylhydrazine has been measured from 4500 to  $400\text{ cm}^{-1}$  using a conventional prism spectrometer [44]. The region below  $1500\text{ cm}^{-1}$  has also been investigated in the liquid and solid states, in solution, and in the gas phase at 393 K (120 °C). The spectra in the gaseous and condensed phases were similar, with the exception of a few bands, and possible reasons for their appearance were suggested. No alteration in the spectrum occurred with a change in temperature, which can be attributed to the occurrence of more than one structural isomer.

### 5.2.1 Molecular Structure of Tetramethylhydrazine

The molecular structure of tetramethylhydrazine has been investigated by electron diffraction in the gas phase [45]. Diffraction intensities can be explained by a mixture of *gauche* and *trans* conformations in a 70:30% ratio. The structure parameters are  $r(\text{C}-\text{H}) = 1.096\text{ \AA}$ ,  $r(\text{C}-\text{N}) = 1.463\text{ \AA}$ ,  $r(\text{N}-\text{N}) = 1.410\text{ \AA}$ ,  $\angle\text{NCH} = 108.6^\circ$ ,  $\angle\text{CNC} = 110.8^\circ$ , and  $\angle\text{NNC} = 113.5^\circ$ . For the *gauche* conformation, the dihedral angle between two vicinal methyl groups was  $78.5^\circ$ .

Based on Molecular Mechanics 3 (MM3) computational studies, the theoretical N—N bond length for tetramethylhydrazine is  $1.436 \times 10^{-10}$  m, indicating that experimental values ( $1.401 \times 10^{-10}$  m) probably err on the low side [46].

### 5.3 Toxicity of Tetramethylhydrazine

Given the tumor-inducing activities of the three lower methylhydrazines, it is not surprising to find that there was the same effect with tetramethylhydrazine when using Swiss mice as test animals [47]. Tetramethylhydrazine hydrochloride predominantly produced blood vessel tumors in 92% of the mice. Trimethylhydrazine or tetramethylhydrazine are not nearly as active carcinogens as SDMH.

## 6 Other Alkylhydrazines and Their Salts

Besides methyl hydrazines, alkylhydrazines with longer alkyl chains and arylhydrazines have been considered as rocket fuels. They do not exhibit any advantage over methylhydrazines and have never seen flight use. Some of the other alkylhydrazines and their hydrazides are being used for the synthesis of heterocyclic compounds.

*tert*-Butylhydrazinium azide [*tert*-BuNH<sub>2</sub>NH<sub>2</sub>]<sup>+</sup>[N<sub>3</sub>]<sup>−</sup> was prepared from *tert*-butylhydrazine and hydrazoic acid [48, 49]. *N,N,N*-Trimethylhydrazinium azide [NH<sub>2</sub>-N(CH<sub>3</sub>)<sub>3</sub>]<sup>+</sup>[N<sub>3</sub>]<sup>−</sup> was prepared via the reaction of silver azide with *N,N,N*-trimethylhydrazinium iodide. Both salts were characterized by XRD, IR, Raman, and multinuclear <sup>1</sup>H-, <sup>13</sup>C-, and <sup>14</sup>N-NMR spectroscopy.

### 6.1 Alkenylhydrazines

Vinylhydrazines and allylhydrazines could be used as intermediates for the synthesis of alkylhydrazines with substituents other than hydrogen in the alkyl groups by addition to the double bond(s) in the alkenyl rests. They could also be used as hypergolic fuels in place of or in mixtures with other alkylhydrazines. If vinylhydrazine or its salts could be polymerized without breaking the N—N bond, one could make a polyvinylhydrazine that should be a good solid-propellant binder [50].

It was not possible to make methylvinylhydrazine by partial reduction of methylvinyl nitrosamine [51, 52]. Instead, 1-ethyl-1-methylhydrazine was obtained.

The reaction of triallylamine with hydroxylamine-*O*-sulfonic acid gave a salt of triallylhydrazine and the triallylhydrazine itself was liberated by reaction with sodium methoxide [53]. Triallylhydrazine was separated by distillation at 358 K at 5 kPa (85 °C at 37 mm Hg). *N,N*-dimethyl-*N'*-allylhydrazine was obtained by a similar method.

## 6.2 Alkynylhydrazines

Hydrazines with extremely high heat of combustion values are obtained by substituting one or several hydrogens with alkynyl (alkyne) groups. Alkynylamines were already examined for the same reason. Alkynylhydrazines were patented as high-energy rocket fuels [54]. According to that patent, (2-propynyl)hydrazine and 1,1-bis-(2-propynyl)hydrazine freeze at approximately 213 and 228 K (−60 and −45°C) and boil at 336–339 K at 2.26 kPa pressure (63–66°C at 17 mmHg pressure) or at 334–336 K at 0.5 kPa pressure (61–63°C at 4 mmHg pressure), respectively. Dimethyl(2-propynyl)amine and allyl-di(2-propynyl)amine freeze at approximately 229 K (−44°C) and 213 K (−60°C), respectively. The compounds possess very high heats of combustion, as shown in Table 3.

**Table 3:** Heats of combustion of alkynylhydrazines.

| Compound                         | Heat of combustion |         |
|----------------------------------|--------------------|---------|
|                                  | kJ/kg              | kcal/kg |
| (2-Propynyl)hydrazine            | 32635              | 7800    |
| 1,1-Bis(2-propynyl)hydrazine     | 37070              | 8860    |
| 1-Methyl-1-(2-propynyl)hydrazine | 34895              | 8340    |
| 1-Ethyl-1-(2-propynyl)hydrazine  | 36230              | 8660    |
| Methyl-di-(2-propynyl)hydrazine  | 41000              | 9800    |
| Dimethyl-(2-propynyl)hydrazine   | 39960              | 9550    |

Data source: [54]

Direct alkylation of hydrazine hydrate in ethanol with propargyl bromide gives 2-propynylhydrazine and 1,1-di(2-propynyl)hydrazine [55]. Efforts, not always successful, were made to synthesize monopropargylhydrazine and *N*-methyl-*N*-propargylhydrazine [56]. Monopropargylhydrazine and unsymmetrical dipropargylhydrazine were evaluated as hypergolic rocket fuels [57].

## 6.3 Preparation of Other Alkylhydrazines

There are 20 conceivable methyl- and ethyl-substituted hydrazines. Only three are available commercially: MMH, UDMH, and SDMH. Until 1973, only 12 additional ones were described in the literature. When the need arose to investigate all 20 compounds, the missing (previously unknown) five alkylhydrazines were synthesized using standard routes [58, 59]. The new hydrazines and their methods of synthesis are summarized in Table 4.

Table 4: Summary of reactions used in syntheses of methyl- and ethyl-substituted hydrazines.

|                             |                                                |                                                        |                                       |                                                                |                                            |                                              |                                         |                                            |

|                             |                                                |                                                        |                                       |                                                                |                                            |                                              |                                         | $\text{Et}_2\text{NN}(\text{Ac})\text{Me}$ |
|                             |                                                |                                                        |                                       |                                                                |                                            |                                              |                                         | $\xrightarrow{\text{LiAlH}_4}$             |
|                             |                                                |                                                        |                                       |                                                                |                                            |                                              |                                         | $\text{Et}_2\text{NN}(\text{Et})\text{Me}$ |
|                             |                                                |                                                        |                                       |                                                                |                                            |                                              |                                         | $\xrightarrow{\text{LiAlH}_4}$             |
|                             |                                                |                                                        |                                       |                                                                |                                            |                                              |                                         | $\text{Et}_2\text{NNEt}_2$                 |

<sup>a</sup> Legend: Ac = acetyl, Et = ethyl, Me = methyl, Ph = phenyl

Lithium aluminum hydride proved to be a useful synthetic tool during this effort because it reduces formaldehyde hydrazones to methylhydrazines and acethydrazides to ethylhydrazines. These methods were preferred over the direct alkylation because they result in fewer by-products.

When preparing tetraalkylhydrazines by  $\text{LiAlH}_4$  reduction of acylhydrazines, the products were frequently contaminated by trialkylhydrazine formed by cleavage of the *N*-acyl bond. This unwanted by-product was converted to a high-boiling acetyl derivative with acetic anhydride, and then the lower-boiling tetraalkylhydrazine, which does not react with acetic anhydride, could be removed by distillation.

### 6.3.1 Preparation of Other Alkylhydrazines (Monoalkylhydrazines)

Higher alkylhydrazines and substituted hydrazines are not used as rocket propellants but are sometimes investigated in stability and molecular structure studies comparing them to MMH or UDMH. All alkylhydrazines are useful reactants in the synthesis of heterocyclic compounds with two or more nitrogens in the ring. Higher alkylhydrazines and substituted hydrazines can frequently be prepared by using the same methods used for MMH. In addition, other methods have been described that produce only poor yields for the lowest member of the alkylhydrazine family. Some of these methods can be used to synthesize alkylhydrazines with substituents in the alkyl group, resulting in more energetic or less toxic hydrazines. A very comprehensive survey article on the preparation and reactions of monoalkylhydrazines contained 363 references [7]. The following hydrazone method can be used, which can start with hydrazine hydrate instead of anhydrous hydrazine:

Reaction rates and activation energies for the reactions of chloramine with *n*-propylamine, *n*-butylamine, or di-*n*-propylamine in liquid ammonia solvent, leading to *n*-propylhydrazine, *n*-butylhydrazine, or *N,N*-di-*n*-propylhydrazine, showed that replacement of the hydrogen in ammonia by an alkyl group greatly enhances the reactivity of the amino compound toward chloramine [60]. At 223 K, replacement of one hydrogen by propyl increased the reaction rate 140-fold. Replacement of two hydrogens by propyl groups increased the rate of reaction with chloramine 460-fold. These reactions led to substituted alkylhydrazines in good yields, although the yields were limited by side reactions of product hydrazines with chloramine. The reaction of amines with chloramine proved to be a generally useful method for the synthesis of alkylhydrazines, as illustrated by the conversion of *n*-hexylamine and cyclohexy-

lamine to the corresponding hydrazines, allylamine to allylhydrazine, ethanolamine to  $\beta$ -hydroxyethylhydrazine, ethylenediamine to  $\beta$ -aminoethylhydrazine, and morpholine to *N*-aminomorpholine [61]. The reaction of glycine with chloramine did not give the desired hydrazinoacetic acid, because the mixture decomposed prematurely. Piperylhydrazine can be obtained by bubbling a chloramine-ammonia mixture at a rate of 0.8 mM/min through 150 mL of piperidine for 45 min, removing the amine salt by filtration and unreacted piperidine by distillation [62]. The yellow oily distillation residue was reacted with benzaldehyde to extract the piperylhydrazine as the corresponding hydrazone in 50% yield. 2-Pentylhydrazine can be obtained by reducing the hydrazone of methyl propyl ketone with hydrogen and platinum oxide [63]. The same method has been used for 3-cyclohexyl-2-propylhydrazine [64]. Sterically bulky groups (*tert*-butyl or benzyl) favor monosubstitution. Although the yields were not economically attractive, the following monoalkylhydrazines have been prepared from the corresponding alkyl bromides and a fivefold molar excess of hydrazine: ethylhydrazine, *n*-butylhydrazine, and *n*-nonylhydrazine [65]. Alkylation of hydrazine hydrate with  $\text{ClCH}_2\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2$  leads to  $\beta$ -diethylaminoethylhydrazine,  $(\text{C}_2\text{H}_5)_2\text{NCH}_2\text{CH}_2\text{NHNH}_2$ , a potential rocket fuel [66].

The reaction of aziridine (ethyleneimine) with hydrazine produces  $\beta$ -aminoethylhydrazine,  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHNH}_2$ , also a potential rocket fuel [67, 68]:

A homologous series of *n*-aliphatic hydrazines, ethyl- through *n*-amyl hydrazines, and isopropyl hydrazine and hydroxyethylhydrazine were prepared from the corresponding amines [1]. The yields were typically around 40% of the theoretically expected yields. The most convenient way to isolate the new hydrazines was in the form of their sparingly soluble oxalates.

### 6.3.2 Preparation of Other Dialkylhydrazines

Some of the methods described for UDMH and SDMH are also applicable to higher dialkyl hydrazines. The following reactions have been used to prepare unsymmetrical dialkylhydrazines:

The Sisler process can be modified by reacting chlorine with a secondary amine first and then reacting the substituted chloramine with aqueous or anhydrous ammonia in the presence of caustic [69–71] or reacting a dialkylchloramine with an excess of ammonia in a pressure bomb [72].

The following alkylhydrazines have been prepared by reaction of chloramine with anhydrous primary and secondary amines: methylhydrazine; ethylhydrazine; isopropylhydrazine; *unsym*-dimethylhydrazine; *unsym*-diisopropylhydrazine; and *N*-aminopiperidine [62]; as well as cyclohexylhydrazine, and butylhydrazine [73]. Surprisingly, the reaction of chloramine with diethylamine resulted only in the formation of monoethylhydrazine because of the loss of an ethyl group. This is in contrast to the formation of 1,1-dimethylhydrazine, 1,1-diethylhydrazine, 1,1-di-*n*-propylhydrazine, and di-*n*-butylhydrazine in 40–50% yield by reaction of chloramine and secondary amines in aqueous solution [74]. The 1,1-dialkylhydrazines were identified as the sparsely soluble oxalates.

Like UDMH itself, most other unsymmetrical dialkylhydrazines can be prepared by reduction of the corresponding secondary nitrosamines. The methods described in the literature vary mostly with regard to the reducing agent used. Thus 1,1-diethylhydrazine was obtained in 75% yield by reduction of the nitrosamine with aluminum flakes and sodium hydroxide [75, 76]. 1,1-Diisopropylhydrazine,  $[(\text{H}_3\text{C})_2\text{C}]_2\text{NNH}_2$ , CAS RN [921-14-2], with a boiling point of 315–316 K at 1.7–2.1 kPa (42–43 °C at 13–16 mm Hg), was prepared by the same method. The catalytic reduction of nitrosamines with hydrogen on a palladium catalyst is applicable to higher dialkylhydrazines as well [77]. The following 1,1-dialkylhydrazines were prepared from the corresponding secondary amines by nitrosation with  $\text{NaNO}_2\text{-HCl}$ , separation of the nitrosamine, and reduction with zinc amalgam [78]: 1,1-diethylhydrazine, 1-methyl-1-*n*-propylhydrazine, 1-methyl-1-isopropylhydrazine, 1-methyl-1-*n*-butylhydrazine, 1-methyl-1-isobutylhydrazine, 1,1-di-*n*-propylhydrazine, and di-*n*-butylhydrazine. Reduction of *N*-nitrosodialkylamines with lithium aluminum hydride in ether gave 1,1-diethylhydrazine or 1,1-diisopropylhydrazine in 55–58% yield [79].

1,1-Diethylhydrazine was obtained by thermal decomposition and treatment with alkali of what was called *diethyl hydroxyurea*,  $(\text{C}_2\text{H}_5)_2\text{N-CO-NHOH}$  [80]. Its reaction product with phenyl isocyanate was a well-crystallized derivative,  $\text{C}_6\text{H}_5\text{-N=C=N-N}(\text{C}_2\text{H}_5)_2$ , melting point 398 K.

The reaction of primary amines with hydroxylamine-*O*-sulfonic acid that leads to alkyl- and arylhydrazines can also be applied to secondary amines to form 1,1-dialkylhydrazines in good yields [81]. 1,1-Diethylhydrazine, 1,1-di-*n*-butylhydrazine, and *N*-aminopiperidine have been prepared by this route. The reaction of hydroxylamine-*O*-sulfonic acid with tertiary amines gave quaternary hydrazinium compounds, such as 1,1,1-trimethylhydrazinium iodide from trimethylamine, hydroxylamine-*O*-sulfonic acid, and hydrogen iodide. These hydrazinium salts can also be precipitated as their well-crystallized oxalates or picrates.

A useful source of free alkyl radicals for kinetic studies is the thermolysis of azoalkanes. Azoalkanes are obtained in over 90% yield by oxidation of 1,2-dialkylhydrazines with mercury(II) oxide in water. 1,2-Diethylhydrazine was prepared in 80% yield by reduction of ethylideneazine with lithium alanate [82]. The azine was first made by reacting an excess of acetaldehyde with hydrazine hydrate.

1,2-Di-*n*-propylhydrazine was prepared by similar methods in 77% yield, and 1,2-diisopropylhydrazine in 81% yield. Mixed dimethyl alkylhydrazines (e.g., 1-ethyl-2,2-dimethylhydrazine) were obtained by reduction of 1-acetyl-2,2-dimethylhydrazine [83].

Direct alkylation with alkylhalogenides, as already discussed for trimethyl and tetramethylhydrazine, can be used to synthesize the higher trialkyl- and tetraalkylhydrazines, also in mixed configurations. Reacting unsymmetrical dibutylhydrazine in ethylene glycol dimethyl ether with butyl bromide in the presence of sodium hydride gave tributylhydrazine in 54% yield and tetrabutylhydrazine in 6% yield [84].

### 6.3.3 Preparation of Dialkynylhydrazines

Triple  $C\equiv C$  bonds derived from acetylene derivatives can increase the energy content of molecules. Thus, instead of physically mixing acetylene and hydrazine, the triple bonds can be included in the alkyl (i.e., alkynyl) groups attached to hydrazine. Monopropargylhydrazine and unsymmetrical dipropargylhydrazine were evaluated as rocket fuels [57].

## 6.4 Preparation and Properties of Tri- and Tetraalkylhydrazines

The preparation of trimethylhydrazine and tetramethylhydrazine is described in Section 4.1. Here we discuss tri- and tetraalkylhydrazines with alkyl groups other than methyl. The reaction of chloramine with tertiary amines results in the formation of 1,1,1-trisubstituted hydrazinium salts [85–87]. The salts of trimethyl-, triethyl-, tri-*n*-propyl-, tri-*n*-heptyl-, 1,1-dimethyl-1-phenyl-, and 1,1-diethyl-1-phenylhydrazine have been characterized as chlorides, hexafluorophosphates, picrates, nitrates, and perchlorates. A summary of quaternary hydrazine compounds was compiled [88]. Paired with different anions, such as dicyanomethanide, some of these quaternary salts can serve as ionic liquids.

In analogy to quaternary ammonium salts, quaternary hydrazinium salts can be converted to hydrazinium hydroxides by reaction with silver oxide. The same method can also be applied to obtain quaternary hydrazinium salts of long-chain aliphatic hydrazines.

Tetraalkylhydrazines can be prepared by photolysis of tetraalkyltetrazenes [39, 89]. Tetramethylmethylenediamine and trimethyltrimethylenetriamine were formed as byproducts.

An amino (hydrazino) group can be protected from unwanted alkylation by acetylation. Acetodimethylhydrazide, obtained from UDMH and acetic anhydride, can be alkylated with ethyl iodide to form a quaternary compound which, on hydrolysis and elimination of one methyl group, gives 1-methyl-1-ethylhydrazine [90]:

The procedure can be repeated with the elimination of the second methyl group, resulting in 1,1-diethylhydrazine-. Similarly, methylpropylhydrazine and 1,1-dipropylhydrazine have been prepared in good yields. 1,2-Diethyl-1,2-dimethylhydrazine can be prepared by reduction of 1,2-diacetyl-1,2-dimethylhydrazine [83].

Substituted *N*-amino-piperidine derivatives were prepared by reaction of quaternary hydrazinium salts with aqueous NaOH, KOH, or Na<sub>2</sub>CO<sub>3</sub> [91]:

where R = methyl, isopropyl, cyclohexyl.

## 6.5 Preparation of Alkylene Dihydrazines

The simplest alkylene dihydrazine, methylene dihydrazine, was prepared by reaction of hydrazine with tris(chloromethyl)amine or the boron trifluoride BF<sub>3</sub> adduct of 1,3,5-trimethylhexahydro-*s*-triazine and characterized spectroscopically [92]. The reaction between methylhydrazine and tris(chlormethyl)amine gave 1,4-dimethylhexahydro-*s*-tetrazine.

Methylene dihydrazine is not very stable. Its homologue, 1,2-dihydrazinoethane (also called ethylene dihydrazine, EDH), can be prepared from 1,2-dichloroethane and an excess of hydrazine hydrate, and has been evaluated as a hypergolic rocket fuel on its own or in mixtures with UDMH [93, 94].

The reduction of nitrosamines can also be used to synthesize aliphatic dihydrazines, aminohydrazines, and aminodihydrazines of general structure H<sub>2</sub>NNR(CH<sub>2</sub>)<sub>*n*</sub>NRX with R = methyl, ethyl, *n*-propyl, or isopropyl groups, *n* = 2 or 3, and X = H or NH<sub>2</sub> [95]. The hydrazines were characterized in the form of their dihydrazones with 4-nitrobenzaldehyde and of hydrazides of aliphatic carbonic acids, and can be used as hypergolic fuels.

## 7 Omega-Substituted C<sub>2</sub>–C<sub>5</sub> Alkylhydrazines

Alkylhydrazines with alkyl groups that contain two to five carbon atoms are of less interest as rocket propellants but are included here mostly for comparison and because of theoretical studies. 1,1-Diethylhydrazine, (C<sub>2</sub>H<sub>5</sub>)<sub>2</sub>NNH<sub>2</sub>, C<sub>4</sub>H<sub>12</sub>N<sub>2</sub>, CAS RN [616-40-0], *M* = 88.15 g/mol, might be a substitute for UDMH with lower vapor pressure and almost equal rocket performance. Very little work has been done on 1,1-diethylhydrazine. Its boiling point is 372 K (99 °C) and its density is 0.8004 g/cm<sup>3</sup> at 293 K (20 °C).

The enthalpy of formation of *N,N'*-di-*n*-butylhydrazine vapor is –59.4 kJ/mol.

If simple alkyl substitution of hydrogens in hydrazine does not result in alkylhydrazine fuels with the desired attributes, the physical and chemical properties of alkylhydrazines can be modified further by substituting hydrogens in the alkyl group with additional hydroxyl, amino, cyano, azido, or hydrazino groups. Alpha substitution in methylhydrazines is not possible because double substitution on methyl groups makes these compounds very unstable. Beta and higher (omega) substitution in higher (C<sub>*n* ≥ 2</sub>) alkylhydrazines leads to a group of alkylhydrazines with interesting physical properties – in particular, much lower vapor pressures, which makes them easier to handle than MMH or UDMH. Typically, only monoalkylhydrazines are modified in this manner, but di-, tri-, and tetraalkylhydrazines could be modified in the same way.

If the alkyl group in C<sub>*n* ≥ 2</sub> alkylhydrazines is substituted, substitution could occur on the alpha-, beta-, or omega carbon atom. For substituted ethylhydrazines, substitution typically occurs at the beta- (2-) position. To avoid confusion, one should always include the position designator beta- or 2- when describing 2-hydroxyethylhydrazine or 2cyanoethylhydrazine-. However, the 2- designator is often omitted because it is known that alpha-substituted hydroxyalkylhydrazines are unstable.

### 7.1 Preparation of Substituted Alkylhydrazines

Substitution of hydrogens in the alkyl groups in alkylhydrazines creates new compounds that have interesting new properties yet inherit the reactivity of alkylhydrazines. These substitutions are typically made on alkyl groups with two or more carbons in the alkyl chain. Substituted methylhydrazines are not very stable. The substituting groups introduced into the new molecules are typically hydroxyl, amino, nitrile, and cyano groups, and are typically in the terminal ω-position, not in the proximal α position.

Monoalkylhydrazines that have a functionalized alkyl group and a formula of H<sub>2</sub>N–NH–R, in which R can be a C<sub>2</sub>–C<sub>6</sub> alkenyl radical, C<sub>2</sub>–C<sub>6</sub> alkynyl radical, or linear or branched C<sub>2</sub>–C<sub>6</sub> alkyl radical carrying at least one functional group selected from a group consisting of OH, C<sub>2</sub>–C<sub>6</sub> alkoxy, C=NH, C≡N, phenoxy, and COOH, can

be synthesized by: **(1)** synthesizing the monoalkylhydrazine  $\text{H}_2\text{N}-\text{NH}-\text{R}$  by reacting a monochloramine with an anhydrous amine of formula  $\text{H}_2\text{N}-\text{R}^2$ ; then **(2)** demixing the solution into an organic phase and an aqueous phase by adding anhydrous sodium hydroxide under cooling; and finally **(3)** isolating the monoalkylhydrazine of formula  $\text{H}_2\text{N}-\text{NH}-\text{R}$  from the organic phase [96].

## 7.2 2-Hydroxyethylhydrazine

2-Hydroxyethylhydrazine, also known as  $\omega$ -hydroxyethylhydrazine, 2-hydrazinoethanol, 2-hydrazonoethanol, HEH,  $\text{H}_2\text{NNHCH}_2\text{CH}_2\text{OH}$ ,  $\text{C}_2\text{H}_8\text{N}_2\text{O}$ , CAS RN [109-84-2], was produced in industrial quantities while it was still being used as a growth retardant to achieve the simultaneous blooming of pineapple plants, compressing the harvest time to a few days instead of several weeks [97, 98]. It is also used as an intermediate in the synthesis of veterinary medicines (furazolidone) and other heterocyclic compounds. Surprisingly, HEH was detected as a naturally occurring antioxidant in the hexane extract of *Cassia fistula* and in the ethanol extract of *Cassia alata* leaves [99, 100]. There are many other naturally occurring hydrazine derivatives, but this one came as a surprise, and may need to be confirmed by other methods.

Only 25 years ago, the HEH nitrate salt was recognized as a potential rocket propellant (monopropellant) ingredient, which has revived the interest in this chemical [101]. In the interim, numerous publications have studied the properties and potential applications of HEH nitrate (see Section 7.2.5.1 on Hydroxyethylhydrazinium Nitrate). Monopropellants containing 2-hydroxyethylhydrazinium nitrate (HEHN) will be described in the chapter “Hydroxylammonium Nitrate-Based Monopropellants” in *Encyclopedia of Monopropellants*.

### 7.2.1 Preparation of 2-Hydroxyethylhydrazine

Hydroxyethylation of hydrazine is achieved relatively easily by reacting it with ethylene oxide, resulting in gradual substitution of one or two hydrogen(s) by the hydroxyethyl group.

Hydroxyethylhydrazine free base can be prepared by reaction of ethylene oxide with a large excess of hydrazine or hydrazine hydrate [102]. Instead of alkylating hydrazine with alkyl halogenides or sulfates, alkylation with bifunctional alkylating agents will result in substituted alkylhydrazines that are useful intermediates in organic synthesis. Reaction of an excess of hydrazine or hydrazine hydrate with ethylene oxide at low pressure gives  $\beta$ -hydroxyethylhydrazine [102]:

This reaction has to be carried out with extreme safety precautions because both reactants are monopropellants in their own right and might explode if overheated. Each of the reactants by themselves have caused numerous accidental explosions. The reaction does not stop at the monosubstituted hydrazine; the nucleophilic ethylene oxide will seek out the free electron pair in HEH and quickly form a disubstituted hydrazine. The more prevalent secondary product forms mostly by 1,1-disubstitution, with only a little forming by 1,2-disubstitution. The difficulty of this reaction is to prevent more than one hydroxyethyl group from attaching itself to the hydrazine molecule. If multiple substitution is not prevented, the resultant dihydroxyethylhydrazines (two possible isomers) are undesirable contaminants in the HEH product.

Hydroxyethyl (hydroxyalkyl) groups can be introduced into substituted hydrazines by reaction with ethylene oxide (or similar alkylloxiranes) [103]:

Hydroxyethylhydrazine free base was available in the US in large quantities while it was still being used as a growth retardant of pineapple and other fruit, allowing all fruit to ripen at the same time and facilitating the harvest. Toxicity considerations have caused farmers to discontinue this application and the chemical is no longer in use, resulting in a supply problem. Hydroxyethylhydrazine was an intermediate in the preparation of a nitrofuran anti-bacterial agent used mostly in veterinary medicine, but that was not sufficient to entice the US chemical industry to keep it in production. For several years, the only source was a chemical company in Mexico, and lately even that source has dried out.

Two different methods for the synthesis of hydroxyethylhydrazine that avoid the use of ethylene oxide were evaluated and compared: Raschig synthesis (the reaction of monochloramine and ethanolamine) and alkylation of hydrazine hydrate by chloroethanol [104]. For the Raschig synthesis, a kinetic and mechanistic study of the reactions of formation and degradation made it possible to identify the products and to establish a reaction model. The optimum conditions for synthesis were defined, as well as the approach to extraction operations. The second part of the thesis examined the alkylation of hydrazine hydrate by chloroethanol with and without the presence of a strong base. The rate laws of the mono- and dialkylation were given. This work was supplemented by a calorimetric study of the enthalpy of solvation and reaction.

The synthesis of HEH by reaction of 2-chloroethanol,  $\text{ClCH}_2\text{CH}_2\text{OH}$ , with an excess of hydrazine also often leads to disubstituted hydrazine instead of only the desired monosubstituted product [105]. To optimize yields of HEH, a study of the kinetics of the reaction of  $\text{N}_2\text{H}_4$  with 2-chloroethanol with and without sodium hydroxide was carried out. The reaction kinetics of the synthesis of 2-hydroxyethylhydrazine (HEH) by alkylation of  $\text{N}_2\text{H}_4$  with 2-chloroethanol with and without sodium hydroxide were derived from a set of experiments [105]. In both cases, the yield of HEH was diminished by a follow-on HEH alkylation (or dialkylation of  $\text{N}_2\text{H}_4$ ), leading to the formation of two unwanted isomers: 1,1-di(hydroxyethyl)hydrazine and

1,2-di(hydroxyethyl)hydrazine. In this study, hydrazine and hydroxyalkylhydrazine alkylations followed SN2 reactions triggered directly by 2-chloroethanol or indirectly in the presence of a strong base by ethylene oxide, an intermediate compound formed by reaction of 2-chloroethanol with alkali. The kinetics were studied in diluted media by quantifying HEH and 2-chloroethanol by GC and GC-MS. The energy of activation parameters of each reaction and the influence of a strong base on the reaction mechanisms were determined. A global mathematical treatment was applied for each alternative reaction, which allowed the reactions to be modeled as a function of reactant concentrations and temperature. In the case of direct alkylation by 2-chloroethanol, simulations were established for semi-batch and batch syntheses, and simulation results were confirmed in experiments for concentrated solutions ( $1.0\text{ M} \leq [\text{2-chloroethanol}]_0 \leq 3.2\text{ M}$  and  $15.7\text{ M} \leq [\text{N}_2\text{H}_4]_0 \leq 18.8\text{ M}$ ). Simulation permitted the prediction of the momentary concentrations of reagents and products, in particular the ethylene oxide concentration in the case of indirect alkylation (this concentration should be kept as low as possible).

2-Hydroxyethylhydrazine can be made by a modified Raschig synthesis, which is the reaction of monochloramine on ethanolamine. The formation of HEH was monitored by UV spectrometry, and the influences of temperature and pH were measured to better understand the kinetics of this reaction [106]. The primary reaction is an SN2-type mechanism, whereas the main unwanted secondary reaction is the oxidation of HEH by monochloramine. This reaction was also monitored by UV spectrometry, and the oxidation product was identified by GC-MS analysis, showing the formation of hydroxyethylhydrazone. The reaction mechanisms and the rate constants were determined, and the results permitted the main reactions occurring during HEH synthesis to be established. These reactions were validated in a concentrated medium with a systematic study of the influences of the molar ratio ( $[\text{HEH}]_0/[\text{NH}_2\text{Cl}]_0$ ), the final sodium hydroxide concentration, and the temperature. A comparison was made with the other (previously published) synthetic process, the alkylation of hydrazine by either chloroethanol or epoxide.

Unless one maintains a very low HEH concentration in the reaction mixture, di(2-hydroxyethyl)hydrazine is always an undesirable by-product of HEH production. Commercially available HEH is only advertised as a 90–95 or 95–98% purity product. Because of the uncertain supply situation for HEH in the US and the resulting dependence on foreign imports, plans have been developed to establish a domestic HEH production facility to satisfy the anticipated HEH and HEHN needs of the US aerospace industry and government agencies [107–109]. The design followed the process outlined in US Pat. 2660607 [102]. The process design was supposed to meet the following constraints:

- (1) The plant should have a minimum production capacity of 200 metric tons per year (MTPY) of HEH.
- (2) The HEH should have a purity of 99% or greater.

The economic analysis was based on many overly optimistic assumptions. In particular, a domestic HEH supply is useless without a simultaneous reliable domestic source of electronic-grade, high-purity, sulfur-free HAN. See also [110].

### 7.2.2 Physical Properties of 2-Hydroxyethylhydrazine

Compared to other alkylhydrazines, HEH is very viscous. Physical properties of HEH are listed in Table 5.

**Table 5:** Physical properties of 2-hydroxyethylhydrazine.

| Property                                 | SI units                                                 | Other units                                                  |

#### 7.2.2.1 Molecular Structure of 2-Hydroxyethylhydrazine

The hydroxyl group is attached to the ethyl substituent in the terminal ( $\omega$ -) position, identified as 2- or  $\beta$ -hydroxyethyl. Theoretically, the hydroxyl group could also be in the 1- or  $\alpha$ -position, but this molecule would be less stable. The molecular structure of 2-hydroxyethylhydrazine is illustrated in Figure 1.

**Figure 1:** Molecular structure of 2-hydroxyethylhydrazine.

Hydroxymethylmethylhydrazine, another isomer with the same empirical formula ( $C_2H_8N_2O$ ), is not stable.

### 7.2.3 Chemical Properties of 2-Hydroxyethylhydrazine

#### 7.2.3.1 Thermal Stability of 2-Hydroxyethylhydrazine

During the attempted distillation of 2-hydroxyethylhydrazine, brisk gas evolution occurred at about 488 K (215 °C), and a mixture of liquids with boiling points in the range 353–423 K (80–150 °C) were distilled [111]. The residue then charred with some violence. Purification of the distilled liquid gave methylhydrazine (MMH) in 25% yield, which was identified by its boiling point, as well as hydrogen sulfate and hydrogenoxalate salts. This is not a good method to make MMH. In this and subsequent decompositions, the presence of 2-aminoethanol was established, and ammonia and hydrazine were identified in the gaseous effluent. Neutral gases were also evolved but were not identified. In order to prevent the decomposition of HEH, it should be distilled only under reduced pressure. Safe distillation conditions are 413 K at 1.2 kPa (140 °C at 9 mm Hg).

For comparison, the thermal decomposition of 1-hydrazino-2-propanol,  $H_2NNHCH_2CHOHCH_3$ , proceeded more smoothly than with 2-hydrazinoethanol, little gas was evolved, and no violent decompositions occurred.

#### 7.2.3.2 Reactions of 2-Hydroxyethylhydrazine

2-Hydroxyethylhydrazine is a useful intermediate in the synthesis of numerous heterocyclic compounds.

The reaction of HEH with acetylene led to an unexpected product, 1-ethyl-3-methyl-1*H*-pyrazole, in 39% yield [112]. The reaction also yielded the expected (2-vinyloxy)hydrazine in lower yield. A similar reaction was carried out in benzene in the presence of anhydrous cadmium acetate as catalyst, and separation of the reaction mixture by vacuum distillation gave isomeric acetaldehyde *N*-(2-hydroxyethyl)hydrazones and 43% ethylidene-2-methyloxazolidin-3-amine [113].

2-Hydroxyethylhydrazine can be the starting ingredient of an interesting cyclization reaction leading to *N*-aminoaziridine [114]:

HEH is a reducing agent. HEH has been evaluated as a less toxic replacement for hydrazine in nuclear fuel element reprocessing for the reduction of actinide elements such as neptunium.

### 7.2.3.3 Analysis of 2-Hydroxyethylhydrazine

2-Hydroxyethylhydrazine can be analyzed by completing an acidimetric titration with methyl orange indicator followed by oxidimetric titration with potassium periodate in borate-, acetate-, or bicarbonate-buffered solution [115].

Contaminants detected in industrial samples of HEH by GC analysis were hydrazine, water, ethylene glycol, and “high boilers” that cannot be separated from each other by simple distillation [116]. The high boilers consisted of mostly 1,1-di(2-hydroxyethyl)hydrazine with some 1,2-di(2-hydroxyethyl)hydrazine. A third constituent of the high boilers peak was possibly 2-(2-hydroxyethoxy)ethylhydrazine, HOCH<sub>2</sub>CH<sub>2</sub>OCH<sub>2</sub>CH<sub>2</sub>NHNH<sub>2</sub>. A technical-grade HEH sample contained only 83% HEH and 15% high boilers.

### 7.2.4 Toxicity of 2-Hydroxyethylhydrazine

2-Hydroxyethylhydrazine free base (in solution) was at one time widely used as a growth retardant of pineapple, but it is suspected to cause tumors in hamsters, but not in mice. It has since been withdrawn from this agricultural application. Solutions of 0.015% 2-hydroxyethylhydrazine were given continuously in the drinking water of 6- and 5-week-old Syrian golden hamsters and Swiss mice for the remainder of their lifetimes [117]. In treated hamsters, 6% of the females and 10% of the males developed hepatomas, whereas the corresponding incidence among untreated controls was 0% in females and 1% in males. The chemical did not increase the incidence of other tumors in hamsters; nor did it result in a detectable tumorigenic effect in mice.

The toxicity of 2-hydroxyethylhydrazine (2-hydrazinoethanol) was investigated in turkey poults 2–6 weeks post-hatch [118]. Significant depression of body weight was evident at concentrations of the chemical as low as 10 ppm. Severe anorexia closely paralleled a highly significant decrease in water intake. A significant increase in the ratio of granulocytes to agranulocytes was seen in poults fed the chemical at a dose of 50 ppm. Under the conditions of this experiment, none of the tissues sampled exhibited pathologic changes consistent with HEH injury. See also [119].

### 7.2.5 2-Hydroxyethylhydrazinium Salts

The HEH salts of several energetic anions, including the HEH nitrate, perchlorate, dinitramide, and nitroformate, were prepared and characterized.

### 7.2.5.1 2-Hydroxyethylhydrazinium Nitrate

2-Hydroxyethylhydrazinium nitrate (HEHN) has gained importance as the water-soluble fuel salt in monopropellants in combination with hydroxylammonium nitrate (HAN) as the oxidizer. Several non-toxic (low vapor pressure) monopropellants have been formulated with HAN and HEHN. One of these, AF-M315E, was the first non-toxic monopropellant launched on a US satellite (GPIM). HEHN is very efficient at lowering the melting point of ADN, and ADN/HEHN binary eutectics (without solvent) have been considered as ionic liquid monopropellants.

### 7.2.5.2 Preparation of 2-Hydroxyethylhydrazinium Nitrate

Hydroxyethylhydrazinium nitrate (HEHN) can be prepared by slowly neutralizing diluted hydroxyethylhydrazine with diluted nitric acid and then stripping off the water at reduced pressure in a Rotavapor. Even after removing all of the water from a HEHN solution, HEHN stays behind as a viscous syrup. The resultant syrup residue does not want to crystallize and often remains in a supercooled ionic liquid state for a long time. For subsequent use as a fuel for monopropellants, it is not necessary to obtain HEHN in the crystallized form as long as one knows how much water is clinging tenaciously to the residue.

The preparation of HEHN as well as the hydroxyethylhydrazinium perchlorate, dinitramide, and nitroformate in millimolar quantities can be done using the simple methods described in a patent [120]. Because the reaction is exothermic, it has to be conducted in a solvent diluent (methanol, ethanol, isopropanol, *n*-propanol, *n*-butanol, water, or acetonitrile) and with active cooling to prevent overheating and decomposition of HEHN. With the stronger acids, HEH will form not only the mononitrate and monoperchlorate but also the dinitrate and the diperchlorate. The monobasic salts of HEH are viscous oils, but the dibasic salts are crystalline solids that are extremely shock and friction sensitive.

If larger quantities of HEHN are needed, the methods for HEH neutralization and HEHN production can be patterned after the methods used for making triethanolammonium nitrate (TEAN), which was once used as an ingredient in the production of XM46 liquid gun propellant.

### 7.2.5.3 Physical Properties of 2-Hydroxyethylhydrazinium Nitrate

2-Hydroxyethylhydrazinium(1+) nitrate has an unusually low melting point (<248 K) and has been classified as an ionic liquid. The viscosity of molten HEHN at 298 K (25 °C) is 248 mPa s (248 cPs).

### Molecular Structure of 2-Hydroxyethylhydrazinium Nitrate

Computational chemistry has been used to help explain the unusual behavior of HEHN with regard to its melting point and density. It was hoped that the structure and low-temperature melting point of HEHN could be copied by other ionic liquids that were intended as energetic ionic liquids and rocket propellants.

2-Hydroxyethylhydrazinium nitrate is a low-melting ionic liquid that has considerable potential for energetic materials applications. Although little experimental data are available in the literature, predictions were made concerning the physical and dynamical properties of this ionic liquid based on previous validation of the molecular force field [121]. As shown in Figure 2, the theoretical liquid density decreases linearly with increasing temperature. The experimentally determined [120] density at 298 K of  $1.42 \text{ g/cm}^3$  is in excellent agreement with the value predicted from simulation,  $1.428 \text{ g/cm}^3$ .

**Figure 2:** Computed density of hydroxyethylhydrazinium nitrate as a function of temperature. (Reproduced and modified from [121].)

The ionic liquid HEHN is expected to exhibit strong hydrogen bonding in the liquid phase. The interaction between the nitrate oxygen atoms and either the hydroxyl hydrogen or the amine hydrogens of 2-HEH<sup>+</sup> showed that the N–H···O interaction was far weaker than the O–H···O interaction. The former occurred at  $\sim 1.9 \text{ \AA}$ , while the latter occurred at the much shorter distance of  $\sim 1.5 \text{ \AA}$ . The  $1.5 \text{ \AA}$  hydrogen bond is very short relative to hydrogen bonds in general, which suggests that this interaction is very strong in the liquid. This was supported by the sharpness and intensity of the  $g(r)$  curve for this peak relative to the N–H···O interaction. The correlations at about  $3.5$  to  $4 \text{ \AA}$  are associated with the neighboring oxygens of the nitrate anion. 2-HEHN is an ionic liquid that is dominated by hydrogen bonding due to the presence of many significant donor/acceptor sites.

### Computational Chemistry Calculations of the HEHN Molecular Structure

Force-field (FF) computations were performed for hydrazine and organic hydrazine derivatives, including MMH, UDMH, monoethylhydrazine, and 2-hydroxyethylhydrazine [122]. The FF computations successfully reproduced a range of equilibrium properties, including vapor–liquid coexistence densities, vapor pressures, enthalpies of vaporization, and critical properties. Using this as a basis, a FF method was also developed for the protonated forms of these species, i.e., hydrazinium cations. Properties of 1:1 energetic salts formed by pairing these cations with the nitrate anion were computed and compared with a limited amount of experimental data. The simulations indicated that the ionic liquid 2-HEHN has significantly slower dynamics than the other hydrazinium ILs.

### Optical Properties of Hydroxyethylhydrazinium Nitrate

#### IR Absorption Spectra of HEHN

The IR spectrum of HEHN shown in Figure 3 has absorption peaks at 1763, 1627, 1394, 1157, 1072, 928, and 823  $\text{cm}^{-1}$ .

**Figure 3:** IR spectrum of 2-hydroxyethylhydrazinium nitrate. (Reproduced and modified from [123].)

The IR spectrum of HEHN is compared to that of HEH in Figure 4; the main difference is the strong absorption peak at 1394  $\text{cm}^{-1}$  due to the nitrate ion. Other samples showed this peak at 1376  $\text{cm}^{-1}$ .

**Figure 4:** Comparison of the IR spectra of HEH and HEHN. (Reproduced and modified from [123].)

### Thermodynamic Properties of Hydroxyethylhydrazinium Nitrate

The most important thermodynamic property of HEHN needed for theoretical rocket performance calculations is its standard enthalpy of formation in the solid or molten state. It helps to have accurate numbers for the standard enthalpy of formation for the parent hydrazine, HEH. Many organizations have used HEHN standard enthalpies of formation of  $-452 \text{ kJ/mol} = -108 \text{ kcal/mol}$  for theoretical performance calculations.

Various extrapolations have been made. One frequently used method is to compare the molar enthalpies of formation of free liquid amines and free liquid hydrazines to those of their solid nitrates and apply a constant conversion addition (subtraction).

#### 7.2.5.4 Chemical Properties of 2-Hydroxyethylhydrazinium Nitrate

2-Hydroxyethylhydrazinium nitrate is an ionic liquid that does not readily crystallize at room temperature. Molten HEHN or concentrated solutions of HEHN can be decomposed on Shell 405 catalysts [124, 125]. The 2-hydroxyethylhydrazinium dinitrate reacts with Shell 405 catalyst in a similar fashion. It should be mentioned that HEHN has been considered not only as a water-soluble fuel in monopropellants but also as a liquid fuel in bipropellant combinations. HEHN and HEHN solutions in acetone have also been considered as a liquid bipropellant fuel in combination with RFNA, NTO, or 98% HTP [123].

### Thermal Decomposition of 2-Hydroxyethylhydrazinium Nitrate

It is impossible to crystallize HEHN at room temperature and it has a glass transition at 216.2 K (−56.9 °C). In the DSC, HEHN showed an onset of exotherm at 442 K (169 °C) and a peak of exotherm at 471 K (198 °C). Although HEHN will probably not be used as a rocket propellant by itself, it is important to have information on its thermal decomposition. The results of these tests with HEHN by itself will then be compared to similar tests where HEHN is mixed with oxidizers such as HAN or AN. For the same reason, strand burning rates of HEHN by itself have been measured so that they can be compared to strand burning rates of monopropellants containing HEHN.

Confined rapid thermolysis (CRT) with two synergistic diagnostic tools, a Fourier transform infrared (FTIR) spectrometer and a time-of-flight mass spectrometer (ToFMS), were used to study the temporal evolution of gases from the condensed phase during the thermal decomposition of HEHN, and to compare this to the decomposition of AN [126]. High heating rates (2000 K/s) could be achieved by enclosing a small sample volume within a confined space. Decomposition of HEHN was assumed to proceed by three different reactions. The processes governing the decomposition of several energetic compounds were found to be autocatalytic in nature, and the autocatalytic agents were the strong  $\text{HNO}_3$  acids generated by the initial decomposition step. The estimated Arrhenius-type parameters of HEHN decomposition are listed in Table 6.

**Table 6:** Estimated Arrhenius-type parameters of HEHN decomposition.

| Reaction                                                                                                                                          | $E_a$ , kJ/mol | Pre-exponential coefficient $A$ |
|---------------------------------------------------------------------------------------------------------------------------------------------------|----------------|---------------------------------|
| $\text{HEHN} \rightarrow \text{HEH} + \text{HNO}_3$                                                                                               | 183.0          | $2 \times 10^{16}$              |
| $\text{HEHN} + \text{HNO}_3 \rightarrow \text{HEH} + 2\text{HNO}_3$                                                                               | 124.8          | $3.9 \times 10^{12}$            |
| $\text{HEH} + \text{HNO}_3 \rightarrow 2.5\text{H}_2\text{O} + 0.42\text{N}_2\text{O} + 1.08\text{N}_2 + 0.042\text{O}_2 + \text{CH}_3\text{CHO}$ | 24.3           | $8.3 \times 10^5$               |

Data source: [126]

Using these parameters, the predicted evolution of decomposition products and the measured concentration profiles agreed fairly well. The activation energy for the unimolecular step in HEHN decomposition was computed to be slightly higher than that of HN. The reaction rate constants for the unimolecular step for HEHN were found to be to two orders of magnitude higher than those of AN.

The thermal decomposition of HEHN was studied using TGA and FTIR spectroscopy [127]. At a heating rate of 10 K/min, two distinct periods of mass loss were observed. First, the mass decreased by 10% in the temperature range of 313–353 K (40–80 °C), which was attributed to the evaporation of water absorbed by the sample. Next, the mass dropped by 75% between 453 and 513 K (180 and 240 °C) because of

HEHN decomposition. The identified product gases were N<sub>2</sub>O, CO<sub>2</sub>, NH<sub>3</sub>, HNO<sub>3</sub>, and NO<sub>2</sub>. Approximately 15% of the initial mass was found to remain in the crucible after 513 K (240 °C). The kinetic rate equation for HEHN decomposition at 50 bar and 561 K, derived from confined rapid thermolysis, was

$$k = 2 \times 10^{16} \text{ s}^{-1} \exp \left( - (183 \text{ kJ mol}^{-1} / RT) \right) = 0.183 \text{ s}^{-1}$$

In a different study of the thermal decomposition of HEHN in a DSC with a heating rate of 5 K/min., there were two exotherms. The onset of the first exotherm was at 443 K (170 °C) and the maximum of the first exotherm peak was at 473 K (200 °C) [128]. The onset of the second exotherm was at 523 K (250 °C) and the maximum of the second exotherm peak was at 563 K (290 °C). When the test was repeated in gold-plated DSC crucibles, the first exotherm was shifted a little and the second exotherm was shifted substantially towards higher temperatures, and the rate of heat release was lower (Figure 5).

The DSC-TGA at a heating rate of 5 K/min initially showed a slow material loss (moisture?), then a substantial material loss beginning at 473 K (200 °C) accompanied

**Figure 5:** DSC thermogram of HEHN decomposition. (Reproduced and modified from [128], with permission granted by Professor Kento Shiota, 24 May 2021.)

**Figure 6:** DSC-TGA thermogram of HEHN decomposition. (Reproduced and modified from [128], with permission granted by Professor Kento Shiota, 24 May 2021.)

by a single exotherm, and then endothermic decomposition until only 5% material remained in the pan (Figure 6).

The composition of the gases evolved during decomposition of HEHN and the variation in gas composition with time and temperature were monitored by MS. The main products were nitrogen ( $m/z = 28$ ), water ( $m/a = 18$ ), and carbon dioxide ( $m/z = 44$ ) (Figure 7). See also [129].

While Figures 5 and 6 above show the heat flow during DTA and the mass loss during TGA at only one fixed heating rate, a more detailed investigation showed heat flow and mass loss curves during heating of HEHN at four different heating rates (Figures 8 and 9) [130, 131]. The shapes of the curves and the onsets of exotherms depend significantly on the heating rate. The two-stage nature of the decomposition reactions is best shown at slow heating rates.

All the techniques used (TGA, DSC, MS, and FTIR spectroscopy) clearly show the existence of two stages of HEHN thermal decomposition. The apparent activation energies determined by a model-based thermal analysis,  $113.7 \pm 1.7$  kJ/mol for the first stage and  $123.6 \pm 2.5$  kJ/mol for the second stage, are relatively close to the value of 124.8 kJ/mol obtained by Chowdhury and Thynell for step 2 in their reaction mechanism (autocatalytic reaction between HEHN and  $\text{HNO}_3$ ).

**Figure 7:** Composition of the gases evolved during decomposition of HEHN. (Reproduced and modified from [128], with permission granted by Professor Kento Shiota, 24 May 2021.)

#### 7.2.5.5 Strand Burning of 2-Hydroxyethylhydrazinium Nitrate

Although HEHN could not sustain ignition at atmospheric pressures despite repeated attempts, it combusted at chamber pressures of 10 and 15 bar with surrounding atmospheres of air and nitrogen, respectively. The effects of variation of pressure on combustion of HEHN strands were studied at pressures ranging from atmospheric to 90 bar [127]. Immediately after ignition, the monopropellant flame above the liquid surface was maintained by the decomposition of HEHN in the condensed phase. Linear burning rates and temperature distributions during combustion of these formulations were investigated with air or nitrogen as the surrounding atmospheres and compared to those of Otto Fuel-II, a torpedo propellant. The intermediate pressure burning range

**Figure 8:** DSC curves of HEHN decomposition at heating rates of 1, 2.5, 5, and 10 °C/min. (Reprinted and modified from [130], with permission from ©2020 Elsevier; permission conveyed through RightsLink.)

**Figure 9:** TGA curves of HEHN decomposition at four different heating rates. (Reprinted and modified from [130], with permission from ©2020 Elsevier; permission conveyed through RightsLink.)

of HEHN extended from 10 to 50 bar, beyond which abrupt rises in the luminosity and temperature of the monopropellant flame were recorded. The low-pressure deflagration limit (LPDL), which determines the low-pressure limit for self-sustained combustion of a propellant, was found to be 15 and 25 bar for HEHN and Otto Fuel-II, respectively. HEHN at 10 bar did not sustain combustion under repeated attempts. The burning rates of HEHN in two different pressure regimes and two different atmospheres are compared to those of Otto Fuel-II and isopropyl nitrate in Table 7.

**Table 7:** Strand burning rates of HEHN in comparison to those of Otto Fuel-II and isopropyl nitrate.

| Compound        | Atmosphere | Pressure, bar | Burning rate laws            |
|-----------------|------------|---------------|------------------------------|
| HEHN            | Air        | 20–50         | $r = 0.032 \times p^{1.15}$  |
| HEHN            | Air        | 60–90         | $r = 0.331 \times p^{0.58}$  |
| HEHN            | Nitrogen   | 20–50         | $r = 0.043 \times p^{1.10}$  |
| HEHN            | Nitrogen   | 70–90         | $r = 0.560 \times p^{0.45}$  |
| For comparison: |            |               |                              |
| IPN             | Air        | 10–50         | $r = 0.0046 \times p^{1.54}$ |
| Otto Fuel-II    | Air        | 20–100        | $r = 0.0063 \times p^{1.31}$ |

Data source: [127]

Theoretical rocket performance calculations indicated that at a chamber pressure of 2 MPa and a nozzle area ratio of 50, the vacuum specific impulse of HEHN would be 252.2 s, better than that of anhydrous hydrazine.

#### 7.2.5.6 Toxicity of 2-Hydroxyethylhydrazinium Nitrate

HEHN and other potential ingredients for hydrazine monopropellant replacements were examined for their toxicity to liver tissue. *In vitro* rat hepatocyte toxicity and bacteria (*Salmonella*) genotoxicity assays were performed on 13 high-energy chemicals that were candidates for potential replacement monopropellants for hydrazine [132, 133]. The chemicals were mostly hydrazine derivatives and amino compounds in the form of their nitrate salts, including HN and HEHN. Responses to hydrazine were used as reference values for ranking the other chemicals. The results in hepatocytes showed a dose-dependent decrease in mitochondrial activity, an increase in lactate dehydrogenase leakage, and depletion of glutathion levels. According to the MTT assay, the hydrazine-containing compounds were the most toxic (HN > DEHN > DHTN > MMHN > HEHN > DAGN > NAGN), and amino-containing compounds and triazole-containing compounds were less toxic. The order of toxicity of hydrazine derivatives in reducing glutathion GSH levels was DHTN > HN > DEHN > MMHN > HEHN > DAGN > NAGN. Results of genotoxicity tests (Ames assay) indicated that HEHN is not mutagenic. Similar measurements were made in another study of HEHN and other chemicals intended as

hydrazine monopropellant or fuel replacements [134]. Quantitative structure–activity relationships for these nitrate salts were derived from *in vitro* toxicity endpoints in primary cultures of isolated rat hepatocytes, and molecular descriptors were obtained using *ab initio* molecular orbital theory [135]. Appendix F of [136] contains a brief summary of the toxicity of HEHN, also published as a separate report [137].

#### 7.2.5.7 Safety Properties of 2-Hydroxyethylhydrazinium Nitrate

The impact sensitivities of three different HEHN samples measured at one laboratory ranged from 44 to 50 kg-cm. The friction sensitivity of HEHN ranged from 176 to 223 N.

#### 7.2.5.8 Applications of 2-Hydroxyethylhydrazinium Nitrate

*Encyclopedia of Monopropellants* will contain a detailed summary of the application of HEHN as a fuel in non-toxic monopropellants, most of which use HAN as the oxidizer. HEHN solutions in UDMH have been considered as hypergolic fuels in bipropellant engines [138]. UDMH/HEHN blends containing a minimum of 30 mass-% UDMH were found to be hypergolic with RFNA or WFNA, respectively.

HEHN by itself and in mixtures with HAN has been tested as a working fluid in electrospray colloid thrusters [139]. The gas-phase behavior of HEHN ions and clusters is important for understanding its potential as an electrospray thruster propellant. The unimolecular dissociation pathways of two clusters were experimentally observed, and theoretical modeling of hydrogen bonding and dissociation pathways was used to help explain those observations.

#### 7.2.5.9 Propellant Mixtures with 2-Hydroxyethylhydrazine

The chapter “Dimethylhydrazines” in *Encyclopedia of Liquid Fuels* includes a summary of fuel blends containing HEH. HEH has been added to UDMH in an effort to decrease its volatility. Physical properties of UDMH/HEH mixtures have been determined for mixtures containing 0–50 mass-% HEH [140, 141].

### 7.3 1,1-Di(2-hydroxyethyl)hydrazine

Unless one always maintains an excess of hydrazine hydrate and a very low HEH concentration in the reaction mixture, 1,1-di(hydroxyethyl)hydrazine is inevitably an undesirable by-product of HEH production. The second ethylene oxide molecule attaches itself at the nitrogen with the lowest electron concentration, which is the one that already carries an alkyl group. Commercial HEH may contain up to 13% of 1,1-di(hydroxyethyl)hydrazine along with a small amount of its isomer 1,2-di(hydroxyethyl)hydrazine.

## 7.4 2-Aminoethylhydrazine

2-Aminoethylhydrazine, also known as  $\beta$ -aminoethylhydrazine, 1-amino-2-hydrazinoethane, 1,2,6-triazahehexane; ethanamine, 2-hydrazino-; AEH,  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHNH}_2$ ,  $\text{C}_2\text{N}_3\text{H}_9$ , CAS RN [14478-61-6], should make a good hypergolic rocket fuel, but it is not readily available and there is no record that it has ever been tested for that application. AEH is isomeric with dimethylenetriamine (1,3,6-triazahehexane), which is not very stable.

Aminoethylhydrazines can be prepared by reaction of ethylenimine or alkylaziridines with excess hydrazine hydrate or substituted hydrazines [142]. Hydrazine hydrate (80%, 900 g) was heated to 363 K (90 °C), then 250 g ethylenimine was dropped in with stirring. After completion of the addition, the temperature was raised to 393 K (120 °C) within 2 h and kept there for 1 h. Distillation gave 245 g 2-aminoethylhydrazine, whose boiling point was 359–360 K at 1.8 kPa (86–87 °C at 14 mm Hg), and 42 g *N,N*-di(2-aminoethyl)hydrazine, CAS RN [89282-54-2P], whose boiling point was 389–391 K at 533 Pa (116–118 °C at 4 mm Hg). (3-Aminopropyl)hydrazine, with a boiling point of 356–357 K at 1.8 kPa (83–84 °C at 13.5 mm Hg), and *N,N*-bis(3-aminopropyl)hydrazine were prepared analogously. The ternary amine (2-diethylaminoethyl)hydrazine has a boiling point of 385–387 K at 6.7 kPa (112–114 °C at 50 mm Hg), and aminoethyl(diethylaminoethyl)hydrazine has a boiling point of 397–399 K at 1.7 kPa (124–126 °C at 13 mm Hg).

Known synthetic procedures for AEH were rechecked, and that of Eiter and Truscheit [142] yielded 42.5% 2-aminoethylhydrazine, AEH,  $\text{H}_2\text{NCH}_2\text{CH}_2\text{NHNH}_2$ , and 17.5% 1,1-di-(2-aminoethyl)hydrazine ( $\text{H}_2\text{NCH}_2\text{CH}_2$ )<sub>2</sub>NNH<sub>2</sub>, whereas that of Kloes and Offe [66] gave only 23.5% AEH [143]. AEH can be characterized by the melting points of its salts: the dichloride of AEH melts at 442–444 K (169–171 °C); the dioxalate of AEH melts at 469 K (196 °C) (decomp.); and the dipicrate of AEH melts at 448–449 K (175–176 °C) (decomp.)

The yield of AEH was as high as 62% when  $\text{H}_2\text{NCH}_2\text{CH}_2\text{OSO}_3\text{H}$  was refluxed first with 4 mol 80% hydrazine hydrate and then reacted with 2 mol NaOH dissolved in 4.5 mol hydrazine hydrate instead of  $\text{H}_2\text{O}$  [144].

## 7.5 2-Cyanoethylhydrazine and Cyanomethylhydrazine

Similar to hydroxyethylation of hydrazine by reaction with ethylene oxide, cyanoethylation is possible by reacting hydrazine with acrylic nitrile [145]. 2-Cyanoethylhydrazine (CEH) was made by reaction of 0.58 mol of a 64% hydrazine solution (i.e., 100% hydrazine hydrate) and 0.5 mol of acrylonitrile. The addition was carried out over a period of 2 h with a maximum temperature of 294 K (21 °C). The resulting mixture was vacuum distilled at 3.5 mm Hg. The first cut of water and hydrazine was discarded and a middle cut consisting of 2-cyanoethylhydrazine boiling at 378 K at

253 Pa (105 °C at 1.9 mm Hg) was collected. It was characterized by NMR, IR, elemental analyses, and its heat of combustion. A similar reaction of MMH with acrylonitrile gave 1-methyl-1-cyanoethylhydrazine (MCEH), which was vacuum distilled at 342 K at 127 Pa (69 °C at 0.95 mm Hg). The product of the reaction of 0.5 mol UDMH in 40 mL of water at 360 K (87 °C) with 0.5 mol acrylonitrile for 2 h, with the temperature reaching that of reflux, was vacuum distilled at 530 Pa (4 mm Hg). The first cut was removed and discarded, and a second fraction with a boiling point of 350–354 K (77–81 °C) at a pressure of 530 Pa (4 mm Hg) was 1,1-dimethyl-2-cyanoethylhydrazine (DMCEH). This product was characterized by NMR, IR, and elemental analyses. The heat of combustion was determined in order to calculate the enthalpy of formation for the product. Cyanoethylhydrazines would perform well as low-vapor-pressure hypergolic fuels for RFNA, but they are not very stable and discolor during storage. Properties of low-volatility  $\omega$ -substituted alkylhydrazines are listed in Table 8.

**Table 8:** Properties of low-volatility  $\omega$ -substituted alkylhydrazines.

| Property                              | CEH                                          | MCEH                                         | DMCEH                                         | HEH                                            |
|---------------------------------------|----------------------------------------------|----------------------------------------------|-----------------------------------------------|------------------------------------------------|
| CAS RN                                | 353-07-1                                     | 352-90-9                                     | 22705-94                                      | 8 109-8-42                                     |

Data source: [145]

Reaction of UDMH with bromoacetonitrile makes 1-cyanomethyl-1,1-dimethylhydrazinium bromide, [(CH<sub>3</sub>)<sub>2</sub>N(CH<sub>2</sub>CN)NH<sub>2</sub>]Br, which can be converted to energetic salts based on the [(CH<sub>3</sub>)<sub>2</sub>N(CH<sub>2</sub>CN)NH<sub>2</sub>]<sup>+</sup> cation and nitrate, perchlorate, azide, 5-aminotetrazolate, and picrate anions [146]. The melting and decomposition points of these compounds were determined by DSC, and sensitivities to impact, friction, and ESD were measured. See also [147–150].

Nitrosation of 1,2-bis(2-cyanoethyl)hydrazine yields 1-nitroso- and 1,2-dinitroso-1,2-bis(2-cyanoethyl)hydrazines. Decyanoethylation of 1-nitroso-1,2-bis(2-cyanoethyl)hydrazine resulted in formation of sodium azide. Dinitrosohydrazine salts were synthesized by dealkylation of 1,2-dinitroso-1,2-bis(2-cyanoethyl)hydrazine [151]:

## 7.6 2-Azidoethylhydrazine

2-Dimethylaminoethylazide (DMAZ) is simple to prepare and is hypergolic with IRFNA, but there is a significant ignition delay. The replacement of the tertiary amine nitrogen in DMAZ with 1,1-dimethyl hydrazine was expected to result in 1,1-dimethyl-2-(2-azidoethyl)hydrazine, (H<sub>3</sub>C)<sub>2</sub>NNHCH<sub>2</sub>CH<sub>2</sub>N<sub>3</sub>, DMAEH, which was predicted to have better rocket performance than DMAZ. DMAEH is anticipated to have a lower vapor pressure than hydrazine. Several attempts at synthesizing DMAEH by different routes have ultimately failed, as only traces of a product were seen at most [152–154]. The end product in most reactions was a solid quaternary salt with the positive charge on the same nitrogen that was also carrying the two methyl groups. In all cases UDMH acted as a strong nucleophile. Attempts to make 2-azidoethylhydrazine, H<sub>2</sub>NNHCH<sub>2</sub>CH<sub>2</sub>N<sub>3</sub>, by starting with hydrazine instead of UDMH also failed. Intermediates for the synthesis were 2-azidoethyl *p*-toluenesulfonate or 1-azido-2-chloroethane with leaving groups such as *p*-toluenesulfonate (*tosylate*) or a halide. It was hoped that either one would react with UDMH to produce the desired DMAEH energetic fuel.

A three-step reaction sequence was developed, beginning with the reaction of UDMH and chloroacetyl chloride with 1,1-dimethyl-2-[2-chloroethyl]hydrazine as an intermediate [155]. Regardless of the conditions (temperatures, reaction times, and varying reactant concentrations) applied, yields were consistently low (18% max.). The hydrazone was formed, but only accompanied by copious amounts of glyoxal bis-(dimethylhydrazine) as a by-product, from which it was difficult to separate.

In analogy to 2-azidoethanol and DMAZ, which have been extensively studied as potential rocket propellants, computational chemistry predicted that 2-hydrazinoethyl azide (2-azidoethylhydrazine, DMAEH) should be a very energetic molecule. In support of experimental efforts to make DMAEH, quantum chemical calculations using a density functional theory method and charge density analysis of amine-azide-based propellants (DMAZ, DMAEH, 2-azido-*N,N*-dimethylcyclopropanamine, 2-azido-*N*-methylcyclobutanamine, and 2-azidocyclopentanamine) were carried out to understand the geometry, bond topological, electrostatic, and energetic properties of each [156]. The electron density distributions revealed the nature of the chemical bonding in these molecules. The charge concentration of the N–N bond attached to the dimethylamino group in DMAEH is very small, confirming that this bond is the weakest among the molecules. The charge imbalance parameters of the molecules showed that the DMAEH molecule is the least sensitive in this series. Surprisingly, upon comparing band-gap energies among the linear molecules, one would predict that DMAZ (4.42 eV) would be less stable than DMAEH (5.58 eV).

## 7.7 Chloromethyldimethylhydrazine

The reaction of UDMH with excess dichloromethane led to the formation of the chloride salt of the 1-(chloromethyl)-1,1-dimethylhydrazinium cation  $[(\text{CH}_3)_2\text{N}(\text{CH}_2\text{Cl})\text{NH}_2]\text{Cl}$ . The metathetical reaction of this intermediate salt with a suitable silver salt provided the nitrate, perchlorate, azide, dicyanamide, and sulfate salts, which were ionic liquids [157].

## 8 1,2-Dihydrazinoethane

Alkylhydrazines with only one hydrazino group per molecule are discussed above. Similar to polyaminoalkanes, we can also make polyhydrazinoalkanes with two or more hydrazino groups attached to a hydrocarbon alkane backbone. Such compounds may have physical properties that make them more desirable than either MMH or UDMH. The simplest representative of this group is 1,2-dihydrazinoethane, but more complex hydrazines such as 1,2,3,4-tetrahydrazinobutane have also been proposed as rocket fuels. Ethylene dihydrazine was initially considered for use as a liquid propellant approximately 50 years ago because of its high apparent density ( $1.09 \text{ g/cm}^3$ ) and positive enthalpy of formation ( $+155 \text{ kJ/mol}$ ;  $+37 \text{ kcal/mol}$ ) [158].

### 8.1 Preparation of 1,2-Dihydrazinoethane

1,2-Dihydrazinoethane, also known as ethylenedihydrazine, 1,2,5,6-tetraazahexane; hydrazine, 1,1'-(1,2-ethanediy)bis-;  $\text{H}_2\text{NNHCH}_2\text{CH}_2\text{NHNH}_2$ ,  $\text{C}_2\text{H}_{10}\text{N}_4$ , EDH, CAS RN [6068-98-0], has been evaluated as a substitute for UDMH or as an additive to UDMH. However, EDH has a substantially higher viscosity than either hydrazine or UDMH. 1,2-Dihydrazinoethane (also called ethylenedihydrazine, EDH) was prepared from 1,2-dichloroethane and an excess of hydrazine hydrate, and has been evaluated as a hypergolic rocket fuel on its own or in mixtures with UDMH [93, 94]. The reactants are immiscible and had to be stirred for 24 h below 312 K. After the reaction mixture became homogeneous, indicating completion of the reaction, the excess hydrazine hydrate was removed by distillation and the product had to be separated from hydrazinium chloride in the residue and recrystallized as the EDH dichloride salt. 1,4-Diaminopiperazine formed as an unwanted by-product. Even in the presence of a large excess of hydrazine, this and other polymeric by-products formed in the reaction. An alternate method of extracting the desired product involved adding sodium hydroxide to the reaction mixture to neutralize hydrochloric acid and liberate all hydrazines, followed by fractionated vacuum distillation. Reported yields were only 52% of the theoretical yield [158]. EDH has not been commercially available since the early 1960s, when Dow Chemical discontinued its pilot plant operation in

Pittsburgh, CA. When it was commercially available, the EDH was of poor quality. The purification of distilled EDH was achieved by formation and recrystallization of either its hydrochloride or oxalate salt. Purification of the oxalate salt was substantially more efficient and was eventually selected as the method of choice. Purification was monitored by neutralization of the oxalate salt followed by capillary column GC analysis of the liberated EDH. One recrystallization from alcohol/water increased the purity from 87% to a nominal 95%. A second recrystallization gave better than 99% pure EDH. The final isolation was achieved by vacuum distillation. The overall yield of this high-purity EDH (> 99%), based on the starting material ethylene dichloride, was only 19.5%.

The structure of the polymer formed as a byproduct during the reaction of ethylene halogenides and hydrazine hydrate has not been identified. Formation of the otherwise useless polymer is maximized if a ternary amine is added to the reaction mixture [159]. Reduction of the polymer with hydrogen did not give the expected ethylenediamine, indicating it does not have a simple linear structure.

The first step of the synthesis of alkylenedihydrazines often leads to the chloride salts of the desired product. The free bases can be liberated by reaction with alkali metal alkoxides. For instance, an excess of a salt was treated with alkali metal alcoholates to give the free bases  $\text{H}_2\text{NNH}(\text{CH}_2)_n\text{NHNH}_2$ . Thus, 102.4 g ethylenedihydrazine dichloride salt ( $n = 2$ ) was added to a solution of 99.5 g  $\text{PrONa}$  in 400 mL  $\text{PROH}$  at 293–298 K (20–25 °C), the suspension was stirred at room temperature for 4 h, the  $\text{NaCl}$  was filtered off, and the filtrate was distilled to give 29.5 g EDH with a boiling point of 361–362 K at 27 Pa (88–89 °C at 0.2 mm Hg),  $n_D^{22} = 1.522$ ,  $\rho = 1.095 \text{ g/cm}^3$  at 22 °C [160].

The isolation and characterization of trimethylene hydrazine and the search for better syntheses for ethylenedihydrazine did not lead to wider use of these chemicals [56].

1,2-Dihydrazino ethane is an alternative low-vapor-pressure (compared to UDMH) hydrazine fuel for hypergolic storable bipropellant combinations. It has been evaluated as a low-vapor-pressure replacement for MMH or UDMH. Aerojet formulated a hypergolic fuel mixture containing EDH and hydrazine in the 1960s [158]. It was intended as a high-density replacement for Aerozine-50.

The reaction of 1,2-dichloroethane with MMH results in the *N*-methyl-substituted dihydrazinoethane  $\text{H}_3\text{CN}(\text{NH}_2)(\text{CH}_2)_2\text{N}(\text{NH}_2)\text{CH}_3$ , which can be used as a low-vapor-pressure substitute for MMH with no loss in rocket performance [161]. Another bishydrazine that was prepared was 1,1'-(butan-1,4-diyl)bis(1-methylhydrazine),  $\text{H}_3\text{CN}(\text{NH}_2)(\text{CH}_2)_4\text{N}(\text{NH}_2)\text{CH}_3$ . Other low-vapor-pressure alkylhydrazines evaluated as substitutes for MMH had  $\beta$ -aminoethyl or  $\beta$ -azidoethyl substituents.

## 8.2 Physical Properties of 1,2-Dihydrazinoethane Mixtures

The physical properties of EDH/hydrazine mixtures are summarized in Table 9. The freezing point of the binary system shows a minimum near 80% EDH. Solutions with EDH have a tendency to supercool and it is difficult to determine the freezing points.

**Table 9:** Freezing points, densities, and viscosities of 1,2-dihydrazinoethane/hydrazine mixtures.

| EDH, % by mass                                | 0      | 20    | 40    | 60    | 80    | 100  |

## 8.3 Physical Properties of 1,2-Dihydrazinoethane

Physical properties of 1,2-dihydrazinoethane are listed in Table 10.

**Table 10:** Physical properties of 1,2-dihydrazinoethane.

| Property              | SI units                         | Other units            |
|-----------------------|----------------------------------|------------------------|
| Molecular mass        | 90.13 g/mol                      | 11.095 mol/kg          |
| Freezing point        | 285.9 K                          | +12.8 °C               |
| Boiling point         | ~515 K                           | ~242 °C (uncertain)    |
| Density               | 1.096 g/cm <sup>3</sup> at 298 K | —                      |
| Vapor pressure        | 10.6 Pa at 334 K                 | 0.08 mm Hg at 61 °C    |
| Viscosity             | 90 mPa s                         | 90 cPs                 |
| Heat of combustion    | 26.09 kJ/g                       | 6235.9 ± 2.7 cal/g     |
| Enthalpy of formation | +137.7 ± 2.1 kJ/mol              | +32.91 ± 0.49 kcal/mol |
| Heat of vaporization  | 77.0 kJ/mol                      | 18.4 kcal/mol          |

Data source: [158]

### 8.3.1 Densities of 1,2-Dihydrazinoethane/N<sub>2</sub>H<sub>4</sub> Mixtures

Higher densities at similar elemental compositions (carbon contents) can be achieved by replacing UDMH in Aerozine-50 with 1,2-dihydrazinoethane (EDH). Densities of this blend, as shown in Figure 10, increase with increasing EDH content. The EDH/AH mixture is known by the designation A-67, Aerozine-67, which is a solution of 32.8 mass-% ethylene dihydrazine in hydrazine. The density of A-67 is 1.071 g/cm<sup>3</sup> at 298 K (25 °C). The heat of solution of EDH in hydrazine is minimal, +9.3 cal/mol at 65.7–34.3 mass-% EDH-AH.

**Figure 10:** Comparison of density data for 1,2-dihydrazinoethane/hydrazine mixtures. (Image created by Schmidt 2016 based on data from [94] and [158].)

### 8.3.2 Viscosities of 1,2-Dihydrazinoethane/ $\text{N}_2\text{H}_4$ Mixtures

Replacing UDMH in Aerozine-50 with a less volatile alkyldiazine such as 1,2-dihydrazinoethane can reduce the vapor toxicity hazard somewhat, but the viscosity increases dramatically, as illustrated in Figure 11.

**Figure 11:** Viscosity of 1,2-dihydrazinoethane/hydrazine mixtures. (Image created by Schmidt 2016 based on data from [94].)

## 8.4 Chemical Properties of 1,2-Dihydrazinoethane

GC analysis of a commercial sample of EDH (distilled once before) showed that the retention times of the four main components were sufficiently close to indicate that purification by fractional distillation would not be successful. The mononitrate of 1,2-dihydrazinoethane has an unusually low melting point and remains a liquid at room temperature. It has all the properties of an ionic liquid.

## 9 Cyclic Hydrazines

Heterocyclic hydrazines, rings with two adjacent nitrogen atoms, are heterocyclic compounds and are covered in the chapter “Heterocyclic and Heterocycloaliphatic Amines” in *Encyclopedia of Liquid Fuels*.

## 10 Arylhydrazines

Although arylamines like toluidine and xylydine have been used as rocket fuels, arylhydrazines have not. Arylhydrazines are more difficult to prepare than arylamines and are more susceptible to autoxidation.

Historically, much more information has been published about the preparation and chemistry of arylhydrazines than about their aliphatic counterparts. The main cause of this is the close interconnection between aromatic hydrazines and their respective azo compounds, which are useful intermediates for dyes and pharma products. The transitions between amine, azoxy, azo, and hydrazo compounds are easily achieved by progressive oxidation and reduction, respectively:

Arylhydrazines are not generally prepared by direct arylation of hydrazine with arylhalogenides, at least not unless the halogen is sufficiently activated by neighboring groups, such as in 2,4-dinitrochlorobenzene, which reacts with hydrazine to form 2,4-dinitrophenylhydrazine, a widely used reagent for the identification of compounds containing carbonyl groups. The halogen in the vicinity of the heterocyclic nitrogen in 2-chloropyridine or 2-chlorophthalazine is also sufficiently active to give the corresponding hydrazines by direct substitution.

Several books and survey articles on organic hydrazines, in particular aromatic hydrazines, have already been published, and we are not attempting to repeat that material herein.

When viewing the toxicity of hydrazines as a family, it is interesting to note that phenylhydrazine is a constituent of agaritine, a glucoside found in the common brown cap mushroom *Agaricus bisporus*, which is consumed in tonnage quantities by the entire world population, apparently without any undue toxic effects. Fresh mushrooms contain about 0.4–0.7 g agaritine/kg = 0.04–0.07 mass-% dry mushroom (we assume 0.055% on average). The annual US cultivated brown cap mushroom consumption is 800 million lb = 362000000 kg wet. Assuming 10% moisture, that is 326000000 kg dry mass containing 180000 kg agaritine, which contains 20880 kg  $N_2H_3$  entity. According to this calculation, more  $N_2H_3$  is eaten than is used as a rocket propellant. Agaritine has been shown to be broken down by enzymes in animal kidneys into the toxic metabolites 4-(hydroxymethyl)phenylhydrazine and 4-(hydroxymethyl)benzenediazonium ion. These metabolites have been shown to cause stomach cancer in mice.

## 11 Alicyclic Hydrazines

The energy content of alkylhydrazines can be increased by replacing *n*-alkyl groups with alkyl groups that contain stressed rings. 1,4-Di(hydrazomethyl)cubane was prepared by reduction of 1,4-cubanedicarboxylic acid dihydrazide with an excess of  $BH_3 \cdot THF$  etherate [162]. The hydrazines were not stable at room temperature but were isolated as their salts. The dihydrazine dioxalate was the most stable salt isolated, but the diacetate, ditriflate, disulfate, and dinitrate were also prepared. The dinitrate was a white solid with a melting point of 468–469 K (195–196 °C). The diperchlorate and dinitroformate salts decomposed after several hours at room temperature.

## 12 Heterocyclic Hydrazines

2-Pyridylhydrazines can be prepared in 36% yield by the direct introduction of hydrazine as sodium hydrazide into pyridine (Py) and subsequent hydrolysis with water [163]. Even better yields (62 and 58%, respectively) can be obtained from 4-methylpyridine or 2,4-dimethylpyridine. Sodium methylhydrazide and sodium *N,N*-dimethylhydrazide give the corresponding disubstituted (26%) and trisubstituted (33%) hydrazines, respectively [164]. The reaction of sodium hydrazide with aromatic nitrogen heterocycles produces hydrazo compounds:

Various azotetrazole salts are used as percussion initiators. Disposal of these salts by treatment with dilute mineral acid may not be without danger because, in the case of silver azotetrazole, a hypersensitive compound may form [165]. Hydrolysis of azotetrazole anion in boiling dilute sulfuric acid gives 5-hydrazinotetrazole, nitrogen, and formic acid:

3,6-Dihydrazino-1,2,4,5-tetrazine would be a good constituent of gas generator propellants due to its high nitrogen content (79%) and high enthalpy of formation (+519 kJ/mol). It can be prepared by reaction of 3,6-diamino-1,2,4,5-tetrazine with hydrazine [166]. Alicyclic hydrazines are the parent compounds of a large family of 1,2-diazoles and 1,2-diazanes [167].

## 13 Alkyldiazenes and Azoalkanes

### 13.1 Alkyldiazenes

#### 13.1.1 Preparation of Alkyldiazenes

Alkyldiazenes ( $\text{R}-\text{N}=\text{NH}$  compounds with one alkyl group, not with two, as in azoalkanes) are not very stable, but the methyl esters of the alkyl azocarbonic acids  $\text{R}-\text{N}=\text{N}-\text{COOCH}_3$  are stable. Boiling points and IR spectra of several alkyl esters of azocarbonic acids ( $\text{R}=\text{H}$ , cyclopropyl, Me, Et, *i*-Pr, *i*-Bu, and *t*-Bu) were determined [168]. These served as intermediates when preparing short-lived diazenes, the IR spectra of which were measured on cooled samples in frozen matrices. Diazenes are likely intermediates in the Wolff-Kishner reaction. They also form as intermediates in the oxidation of alkylhydrazines.

## 13.2 Azoalkanes

Azoalkanes exist in two structural isomers where the two alkyl groups are either on the same side (*cis*) or on opposite sides (*trans*) of the plane defined by the double bond.

### 13.2.1 Preparation of Azoalkanes

Azoalkanes,  $R-N=N-R$ , are obtained as intermediates in the oxidation of 1,2-dialkylhydrazines. The simplest member of this group is azomethane. Azomethane was detected in the exhaled air of 1,2-dimethylhydrazine-treated rats [169]. Azomethane may form as an unwanted intermediate during industrial MMH synthesis by the Raschig route, and may have been the cause of accidents in MMH production plants. In contrast to the azoaranes (aromatic azo compounds), the azoalkanes are unstable and may decompose explosively. This explosive property is similar to that of diazomethane  $H_2CN_2$ , which is usually handled only in dilute solutions.

### 13.2.2 Physical Properties of Azomethane

Azomethane can be recognized by its Raman spectrum, which is quite different from that of SDMH [170].

### 13.2.3 Decomposition of Azomethane

Azomethane,  $H_3C-N=N-CH_3$ ,  $C_2H_6N_2$ , is a relatively simple molecule, but notoriously unstable. One would not want to use it as a rocket propellant, and one must avoid its formation as a byproduct of other reactions by all means. The decomposition of azomethane is discussed here only because the accumulation and explosive decomposition of azomethane is a potential problem in the production of MMH and has been the cause of accidents.

Similar to methyl azide, which also has no practical application value, azomethane decomposition was studied mostly to satisfy academic curiosity. It is a ready source of methyl radicals, which can trigger all kinds of other reactions. In addition to studying the decomposition of azomethane in the homogeneous gas phase, many studies also looked at the decomposition of azomethane adsorbed on metal surfaces. Azomethane decomposition was once studied because someone was planning to use it as a rocket propellant (which is NOT a good idea!). The kinetics of azomethane decomposition have been studied extensively because, similar to dinitrogen pentoxide, it is a relatively simple reaction. The decomposition of azomethane is a reaction of first order, but the rate decreases at low pressure [171, 172]. The main reaction during decomposition of azomethane leads to ethane and nitrogen:

Side reactions lead to ethylene and methane or to ethylene and hydrogen:

Ethane and nitrogen are reaction products in the decomposition of azomethane, but adding ethane and nitrogen to the azomethane before heating it had little effect on the kinetics and did not retard the decomposition reaction [173].

Helium addition activated azomethane, being 0.12 times as effective as azomethane itself. If the azomethane decomposition is a chain reaction, the chain is very short, and its length is independent of temperature and pressure over the range studied [174].

The products of low-pressure decomposition of azomethane were analyzed by fractionated condensation at dry ice and liquid nitrogen temperatures [175].

The activation energy of azomethane decomposition in the temperature range 563–613 K (290–340 °C) is 220 kJ/mol (52.5 kcal/mol). Tetramethylhydrazine may form as an intermediate during the reaction [176].

Azomethane decomposition can also be initiated by photolysis [177]. The quantum yield of nitrogen formation was found to be unity and independent of temperature.

The rapid pyrolysis of azomethane was studied in a shock tube over the temperature range 800–1300 K [178]. Concentrations of the azomethane in argon were 1–3%. The rate of decomposition in the incident shock region was followed spectrophotometrically at  $\lambda = 338$  nm. It was estimated that, under shock conditions, the depletion of the reactant due to a chain mechanism was negligible compared to that due to the unimolecular decomposition. Due to the exothermicity of the overall reaction (products:  $\text{N}_2$  and  $\text{C}_2\text{H}_4$ ), only average rate constants could be evaluated from the recorded oscilloscope traces. These were found to fall well within the extrapolations of the two most recent low-temperature studies, based on a strict Arrhenius rate vs temperature relationship.

The explosive decomposition of azomethane was studied experimentally in an apparatus that permitted the simultaneous, time-resolved measurement of pressure, the local gas temperature at the center of a spherical reaction vessel, and the local gas temperature near the vessel wall [179]. The explosion-limit pressure could be bracketed closely, and the pre-explosion pressure and temperature rise, the maximum stable temperature rise, the length of the induction period, and the course of the fast but non-explosive decomposition were measured at temperatures from 605 to 714 K and for some mixtures with added  $\text{H}_2$ , He,  $\text{N}_2$ , and NO. NO was added as a free-radical scavenger. At temperatures between 636 and 687 K, the records indicated a thermal explosion, i.e., the temperature at the center rose exponentially just before the onset of explosion and a large maximum temperature rise of 40–45 °C was measured for the

slow reaction just below the limit. From the temperature dependence of the limit, the maximum temperature rise, and the temperature rise well below the limit as a function of initial concentration, an activation energy of 134 kJ/mol (32 kcal/mol) was obtained, in marked disagreement with a literature value of 213 kJ/mol (51 kcal/mol) from slow isothermal decomposition.

The decomposition of azomethane is a complex process, but work showed that the residual fully NO-inhibited reaction has all the features of a unimolecular reaction. This residual reaction was treated using a quantum mechanical harmonic version of a theory of unimolecular reactions [180]. Extrapolation to infinite pressure gave

$$\log k_{10\infty} = 17.32 - 55500/2.303RT$$

In accordance with the high pre-exponential factor (and hence high entropy of activation), a very loose activated complex was postulated, involving free rotations of the two methyls and the central nitrogen. Two models of this complex were considered: one having a planar methyl and the other a tetrahedral methyl. Theory also predicted an activation energy fall-off with pressure that is, on the whole, in accord with the rather limited experimental data.

The thermal decomposition of azomethane has been studied in a static system at temperatures between 523 and 593 K (250 and 320 °C) and at pressures between 0.67 and 53.6 kPa (5 and 402 mm Hg), with particular attention paid to identification of products [181]. Major products, in decreasing order of importance, were nitrogen, methane, ethane, methylethyldiimide, dimethylhydrazone, propane, tetramethylhydrazine, ethylene, methylpropyldiimide, and methylethylhydrazone. Carbon balance at the lowest pressure and highest temperature was 92%, but decreased with increasing pressure and decreasing temperature owing to the formation of a polymer. A fairly simple mechanism should account reasonably well in the decomposition for a short chain reaction propagated by the free radical  $\text{CH}_3\text{N}=\text{NCH}_2^\bullet$ , and for the five most abundant products except ethane. It turns out that there may be a second source of ethane:

Ethyl radicals are also shown to be responsible for the formation of propane, ethylene, methylethylhydrazone, and methylpropyldiimide. The radical  $\text{CH}_3\text{N}=\text{NCH}_2^\bullet$  decomposes to  $\text{CH}_3 + \text{CH}_2 + \text{N}_2$ , and the methylene radical (probably both singlet and triplet) can yield  $\text{C}_2\text{H}_5^\bullet$  at low pressure and high temperature and mostly polymer at high pressure and low temperature.

The rate constant of azomethane decomposition in argon was measured at temperatures of 820–1400 K, pressures of 0.25–7.5 atm, and initial azomethane concentrations of 40–2000 ppm [182]. The amount of azomethane reacted was estimated via UV absorption at the vacuum UV boundary ( $\lambda = 198 \text{ nm}$ ), and the concentration of  $\text{CH}_3^\bullet$  radicals resulting from azomethane decomposition was monitored by absorption at

$\lambda = 216$  nm. The observed temperature dependence of the azomethane decomposition apparent rate constant,

$$k_1 = 10^{11.3} \exp(-33.5/RT) \text{ s}^{-1}$$

was in good agreement with the literature. The low values of the activation energy and pre-exponential factor are unusual for classical monomolecular decomposition. This confirms the assumption that azomethane decomposition at high temperatures takes place via a concerted mechanism.

The decomposition of azomethane has been investigated over a wide range of different conditions and in the presence of various additives, but what is really needed is a study of the effect of azomethane on the decomposition of methylhydrazine and *vice versa*. Such a study has not yet been done. Methyl radicals formed during the decomposition of azomethane are likely to trigger the decomposition of MMH. Active intermediates in the decomposition of azomethane most likely also play a role in the decomposition of MMH, SDMH, and UDMH.

## 14 Alkyltriazanes and Alkyltriazenes

Connecting alkyl groups to a chain of three nitrogen atoms could lead to NH homologues of alkylhydrazines, but connecting three nitrogen atoms in a row leads to unstable compounds unless they are stabilized by resonance with adjacent aromatic structures. In that case, there is usually a  $\text{—N=N—}$  double bond in the chain. Triazenes are more stable than triazanes.

### 14.1 Preparation of Alkyltriazenes

Surprisingly, the reaction of UDMH and chloramine does not lead to dimethyltriazene; a sequence of reactions leads to tetramethyltetrazene as the ultimate product [183]. The chloramine acts just like an oxidant, and the same result can be achieved by using another oxidizer.

While the free dimethyltriazane is not stable, stable 2,2-dimethyltriazanium chloride can be prepared by the reaction of UDMH with chloramine [184]:

If samples of this salt are needed for comparison purposes, it can be prepared in good yield by reaction of UDMH with chloramine in ethereal solution. It is stable at room temperature and reacts with neither ammonia nor UDMH. It can be recrystallized from UDMH, in which it is moderately soluble. Replacing the chloride anion with trinitroformate ion results in the formation of an energetic salt.

1,3-Dialkyltriazenes  $R-NH-N=N-R$  (e.g., 1,3-dimethyltriazene) can be obtained as a magnesium complex intermediate by reacting methyl azide with a Grignard reagent. The solution in ether can be kept at low temperature, but the free pure triazene is unstable. Trimethyltriazene complexes with the chlorides of copper(I), zinc, boron, aluminum, silicon, tin, titanium, zirconium, and phosphorus were found to be stable (at least below 373 K) and were well characterized [185].

*Ab initio* and DFT methods were used to compute the theoretical enthalpies of formation of solid ionic compounds derived from nitrogen-rich salts of the 2,2-dimethyltriazanium cation and other nitrogen-rich ionic compounds [186]. The crystal structure and hydrogen-bonding networks of the nitroformate salt of the 2,2-dimethyltriazanium cation were selected as examples for detailed discussion.

## 14.2 Alkyltriazanium and Alkyltriazenium Salts

The enthalpies of formation of dimethyltriazanium salts were calculated from the heats of combustion and solution (in  $H_2O$ ) [187, 188] (Table 11).

**Table 11:** Enthalpies of formation of dimethyltriazanium salts.

| Compound name                  | Formula                     | Enthalpies of formation |          |
|--------------------------------|-----------------------------|-------------------------|----------|
|                                |                             | kJ/mol                  | kcal/mol |
| Dimethyltriazanium chloride    | $[Me_2N(NH_2)_2]^+ Cl^-$    | -88.6                   | -21.17   |
| Dimethyltriazanium nitrate     | $[Me_2N(NH_2)_2]^+ NO_3^-$  | -145.7                  | -34.82   |
| Dimethyltriazanium perchlorate | $[Me_2N(NH_2)_2]^+ ClO_4^-$ | -69.7                   | -16.66   |
| Dimethyltriazanium ion         | $[Me_2N(NH_2)_2]^+$         | -101.6                  | 24.29    |

Data source: [187]

Triazenes can be stabilized by attaching heterocyclic rings to either end in the 1,3-positions such that the electron cloud of the  $-N=N=N-$  bridge interacts by resonance with the electron clouds in the ring systems, forming compounds such as 1,3-bis(1-methyltetrazol-5-yl)triaz-1-ene and 1,3-bis(2-methyltetrazol-5-yl)triaz-1-ene by diazotization of 1-methyl-5-aminotetrazole or 2-methyl-5-aminotetrazole using only half an equivalent of sodium nitrite [189].

## 14.3 Nitrotriazanes and Nitrotriazenes

Attaching one or two nitro groups to triazane or triazene creates molecules that contain four or even five nitrogen atoms in a chain. An attempt was made to synthesize the ammonium salt of 1,3-dinitrotriazene, (also known as dinitramidoamine,

di(nitramido)amine, and 1,1,5,5-tetraoxoazapentene(2)), but without success [190]. Theoretical calculations were performed in an effort to see if it might be more stable than ADN, which contains just one or two fewer nitrogens. This salt is also known by its acronym, ADNA, but it remains elusive.

## 15 Tetraalkyltetrazenes

### 15.1 Preparation of Tetraalkyltetrazenes

Tetramethyl-2-tetrazene, also known as  $(\text{H}_3\text{C})_2\text{N}=\text{N}=\text{N}(\text{CH}_3)_2$ ,  $\text{C}_4\text{H}_{12}\text{N}_4$ , TMTZ, CAS RN [39247-67-1],  $M = 116.168 \text{ g/mol} = 8.6080 \text{ mol/kg}$ , has been considered as a low-vapor-pressure replacement for MMH or UDMH in hypergolic bipropellant combinations [191].

Tetramethyl-2-tetrazene usually forms as an unwanted autoxidation product in UDMH that has been exposed to air for too long. The contamination of UDMH by tetramethyl-2-tetrazene is usually quickly recognized as it causes yellow discoloration. It has a characteristic absorption band at  $2360 \text{ \AA}$ .

Tetramethyl-2-tetrazene (and similarly tetraethyl-2-tetrazene) can be prepared by oxidation of UDMH (or 1,1-diethylhydrazine) in ether by gradual addition of mercury(II) oxide [39, 192]. It boils at  $305 \text{ K}$  at  $2 \text{ kPa}$  ( $32^\circ\text{C}$  at  $15 \text{ mm Hg}$ ) and has a UV absorption maximum at  $277 \text{ nm}$  in ethanol. The shape of the absorption spectrum differs in solvents of different acidities. Tetramethyltetrazene forms salts and adducts, some of which are stable enough that melting points can be obtained: picrate (m.p.  $353 \text{ K}$ ), hydrogen oxalate, and 1:1 adducts with  $\text{CdCl}_2$ ,  $\text{CdBr}_2$ , and  $\text{HgCl}_2$ . Oxidation of 1,1-dialkylhydrazines with potassium bromate leads to tetraalkyltetrazenes [193, 194].

Tetramethyl-2-tetrazene was initially obtained as a pale-yellow liquid by oxidation of UDMH with  $\text{HgO}$ . The use of toxic and expensive  $\text{HgO}$  can be avoided by oxidizing UDMH with chloramine instead of  $\text{HgO}$  [195–199]. The UDMH solution should be acidified to a slightly basic pH by addition of hydrochloric acid. TMTZ spontaneously demixes from the aqueous medium and can be easily separated from the unreacted UDMH, which can be recycled. The crude TMTZ is 95% pure and the yield is 90%. A potential by-product of the reaction of UDMH with chloramine is formaldehyde dimethylhydrazone [200].

The otherwise very unstable tetramethyltetrazene can be stabilized by forming Lewis-type complexes with Lewis acids, such as trimethylaluminum or triethylaluminum [201]. The adducts are clear, colorless liquids that can be distilled under high vacuum. Similar compounds can be obtained with hydrazine and alkylhydrazines [202]. TMTZ forms a simple salt with hydrochloric acid and a quaternary salt with methyl iodide where the positive charges are located at the two terminal nitrogen atoms [203].

The dimerization of 1,1-dimethyldiazonium and 1,1-diethyldiazonium ions resulted in the random formation of tetramethyltetrazene, 1,1-diethyl-4,4-dimethyltetrazene, and tetraethyltetrazene [204]. Even three-component (Me, Et, Pr) and four-component (Me, Et, Pr, and Bu) mixtures were studied, and mixtures of up to ten different tetraalkyltetrazenes were successfully separated.

Tetramethyltetrazene has been proposed as a hypergolic fuel substitute for the more volatile and more toxic MMH or UDMH. The energy content of tetramethyltetrazene can be improved by replacing one or more methyl groups by azidomethyl groups [205]. The most energetic derivative is 1,1',4,4'-tetraazidomethyl-2-tetrazene (TMTZ), which can be made using the iodosylbenzene/trimethylsilyl azide couple. This one-step synthesis has led to two azido derivatives: 1-azidomethyl-1',4,4'-trimethyl-2-tetrazene (MATMTZ) and 1,4-di(azidomethyl)-1,4-dimethyl-2-tetrazene (DADMTZ). The decomposition of these two compounds in solution at different temperatures was studied using proton NMR analysis and quantitative NMR. Results showed that DADMTZ was more stable than MATMTZ.

Aminoguanidine is a useful intermediate for the synthesis of numerous high-nitrogen compounds. Aminoguanidine sulfate or hydrogen carbonate and sodium nitrite react in a slightly acidified (with acetic acid) solution to form “tetracene” through aminotetrazole and its diazo salt [206, 207]:

The more accurate designation for this compound is 1-(5-tetrazolyl)-4-guanyltetrazene. It forms shock-sensitive heavy-metal salts with silver or copper.

5,5'-Azobistetrazole and its heavy-metal salts are friction sensitive and are used in percussion primers. Azotetrazole is made by oxidizing aminotetrazole in alcoholic solution with permanganates or peroxydisulfates [208] (see also the chapter “Heterocyclic and Heterocycloaliphatic Amines” in *Encyclopedia of Liquid Fuels*). Azotetrazole is acidic and forms highly energetic salts with a variety of bases. The acid hydrolysis of azotetrazole (5,5'-azoditetrazole) anion with dilute acids gives 5-hydrazinotetrazole. However, other high-nitrogen products have also been isolated, one of which is explosive [165].

## 15.2 Physical Properties of Tetramethyltetrazene

The heat of combustion of tetramethyltetrazene is  $3521 \pm 1 \text{ kJ/mol}$  ( $841.47 \pm 0.21 \text{ kcal/mol}$ ). From this number, the enthalpy of formation can be calculated as  $\Delta H_f^{298} = +231.5 \text{ kJ/mol} = +55.34 \text{ kcal/mol}$  [209]. Other sources list exactly the same enthalpy of formation [210].

Boiling points of tetramethyltetrazene at different pressures have been reported. Boiling at 403 K (130 °C) at sea-level pressure results in decomposition. It is safe to distil it at 317 K at 4 Pa (44 °C at 30 mm Hg). Tetramethyl-2-tetrazene boils at 305 K at 2 kPa (32 °C at 15 mm Hg) and has a UV absorption maximum at 277 nm in ethanol [192]. The shape of the absorption spectrum differs in solvents of different acidities. Tetramethyltetrazene forms salts and adducts, some of which are stable enough that melting points can be obtained, for instance a picrate with a melting point of 353 K, a hydrogen oxalate, and 1:1 adducts with  $\text{CdCl}_2$ ,  $\text{CdBr}_2$ , and  $\text{HgCl}_2$ . Titration of tetramethyltetrazene with a Lewis acid ( $\text{BF}_3$  etherate in benzene or  $\text{AlCl}_3$  in chloroform) using crystal violet as an indicator gave sharp end points at molecular ratios of 1:1.

The density of pure TMTZ was  $\rho = 0.899 \text{ g/cm}^3$ , close to that of MMH ( $0.880 \text{ g/cm}^3$ ) [199]. In the IR spectrum, it exhibited a medium band at  $1467 \text{ cm}^{-1}$  ( $\text{N}=\text{N}$ ) and one very sharp band at  $995 \text{ cm}^{-1}$ . In the DSC, TMTZ melted at ca. 248 K (–25 °C) and decomposed at around 426 K (153 °C). The UV spectrum in an aqueous buffered solution (borax buffer, pH 9) featured two absorption bands at 248 nm ( $\epsilon = 5234 \text{ L mol}^{-1} \text{ cm}^{-1}$ ) and 277 nm ( $\epsilon = 7170 \text{ L mol}^{-1} \text{ cm}^{-1}$ ), but only one band was observed in ether (279 nm,  $\epsilon = 9450 \text{ L mol}^{-1} \text{ cm}^{-1}$ ). From the heat of combustion determined in a calorimeter, a standard enthalpy of formation of liquid TMTZ of  $214.37 \text{ kJ/mol}$  ( $51.20 \text{ kcal/mol}$ ) was calculated, which was in the same range as a literature value of  $55.34 \text{ kcal/mol}$ . The vapor pressure of TMTZ at 293 K (20 °C) was 875 Pa (6.57 mm Hg), lower than that of hydrazine and much lower than that of MMH. MMH had a vapor pressure of 4.98 kPa at 293 K (37.35 mm Hg at 20 °C).

Tetramethyl-2-tetrazene and tetraethyl-2-tetrazene in ethanol have absorbance maxima at 277 and 285 nm with molar absorptivities of  $8.3 \times 10^3$  and  $7.6 \times 10^3$ , respectively [192].

Repetitive recording of tetramethyltetrazene spectra in aqueous solution as a function of pH showed that the peak at 277 nm/pH 8.89 is eventually replaced by a peak at 248 nm/pH 3.34 with two distinct isosbestic points at 260 and 210 nm [211].

### 15.3 Decomposition of Tetramethyltetrazene

Some of the radicals and molecule fragments that occur during UDMH decomposition can again be observed during thermal decomposition of tetramethyltetrazene [212]. Fifty-four mass spectrometer runs were carried out at six different temperatures. At 2.4 Pa (0.018 Torr) and 400–420 K, the reaction was first order and the rate equation was

$$\log k = 11.64 - \frac{31900}{2.303RT} \quad \text{s}^{-1}$$

The activation energy was  $133 \text{ kJ/mol}$  ( $31.9 \text{ kcal/mol}$ ). This reaction is of interest for the preparation of tetramethylhydrazine.

Tetramethyltetrazene will decompose as soon as it comes into contact with monometallic noble metal (Pt and Ir) or bimetallic (Pt-Cu and Pt-Zn) catalysts deposited on alumina [213]. The addition of a transition metal such as Zn on Pt/Al<sub>2</sub>O<sub>3</sub> enhances the catalytic activity. A catalyst able to decompose TMTZ at 373 K (100 °C) (no less than 70 °C below the thermal decomposition temperature) was thus obtained and catalyzed the formation of molecular nitrogen, amines, and tetramethylhydrazine. See also [214].

#### 15.4 Toxicity of Tetramethyltetrazene

One of the autoxidation products of UDMH is tetramethyltetrazene, TMTZ, which is a contaminant of UDMH, and may also form in the blood and plasma of UDMH-treated animals.

Intraperitoneal administration of <sup>15</sup>N isotope-labeled TMTZ was performed in mice to define its toxicokinetics and tissue distribution [196, 215]. In two separate test series, mice were injected with TMTZ at a dose of 300 mg/kg and were sacrificed after 1 and 14 d, respectively, and blood and tissue samples were analyzed. A liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) assay was developed to determine TMTZ levels in biological samples. The elimination rate constant suggested that TMTZ was very quickly eliminated from the body. The results of tissue distribution experiments indicated that TMTZ underwent rapid distribution into limited organs such as the liver, kidney, and brain. Administration of TMTZ did not cause death or loss of weight in the mice examined. The mice also did not behave differently than usual, or relative to the control population.

Various cellular animal and human models were exposed to TMTZ and to the reference compound MMH to test their cytotoxicities [216]. There were no cytotoxic effects following exposure to TMTZ in animal as well as human models. The TMTZ molecule had little impact on cellular viability and proliferation of rodent and human dermal and hepatic cell models. TMTZ did not produce any metabolomic effects and appeared to be a promising alternative to MMH.

#### 15.5 Applications of Tetramethyltetrazene

Tetramethyltetrazene has been tested as a hypergolic fuel with IRFNA in a 1100-N (250-lb<sub>f</sub>) rocket engine at 2.07 MPa (300 psi) chamber pressure, and compared to anhydrous hydrazine and UDMH [217]. Six test firings with O/F ratios from 2.42 to 3.19 gave a specific impulse near to 215 s, less than that of hydrazine or UDMH.

While tetrazoles and tetrazole derivatives are surprisingly stable and widely used in various propellant formulations, the open-chain tetrazenes lack stability and must be stabilized by attaching groups that lead to resonance stabilization of the molecule.

One exception is 1,1,4,4-tetramethyltetrazene(2), which is an oxidation product of UDMH and is readily available. Tetramethyltetrazene has even been suggested as a low-volatility replacement for UDMH in hypergolic propellant combinations [217–219].

## 15.6 Alkyltetrazanium and Alkyltetrazenium Salts

Salts derived from alkyltetrazenes with chloramine and strong acids, in particular oxyacids, have been examined as potential propellant ingredients. These include the salts derived from 1,1,4,4-tetramethyl-2-tetrazene and nitric, perchloric, picric, and hydrazoic acids [203, 220]. Most of these syntheses start out by oxidizing UDMH, which leads to the formation of 1,1,4,4-tetramethyl-2-tetrazene.

# Amides and Imides

## 1 Amides

Amides contain the  $\text{—CO—NH—}$  linkage and are usually formed from carboxy acids or carbonyl chlorides with amines or ammonia. Polyamides such as Nylon are known as polymers with very desirable mechanical properties, although they are not used as binders in rocket propellants. Imides contain a  $\text{C=NH}$  linkage and will be discussed in the section “Imides” following the section “Amides.”

The sections “Amides” and “Imides” are arranged in order by the number of carbon atoms in the core of the molecule next to the  $\text{—CO—NH}_2$  group (not including the carbon in the  $\text{—CO—NH}_2$  group in the total count).

Amides and imides carrying nitro groups, such as nitroguanidine, are of particular interest as energetic materials. Many of these compounds described in this section were primarily developed as explosives, but they can potentially be used as replacements for RDX or nitroguanidine, NQ, in composite modified double-base (CMDB) propellants, or as triple-base propellants. Most amides and imides and their salts are useful sources of nitrogen in gas generants for airbag inflators.

## 2 Formamide and Formamide Derivatives

### 2.1 Formamide

Formamide,  $\text{HCONH}_2$ ,  $\text{CH}_3\text{NO}$ , CAS RN [75-12-7], also known as methanamide, is an amide derived from formic acid,  $\text{HCOOH}$ . It could also be considered as the aldehyde of an amino group. The molecular structures of formamide and its two methyl derivatives are shown below.

Formamide is a clear liquid which is miscible with water in all proportions and has an ammonia-like odor. When heated with dehydrating agents, it converts to hydrocyanic acid,  $\text{HCN}$ . It can be used as a non-aqueous solvent, but as such does not have the same desirable solvent properties as its dimethyl derivative, dimethylformamide (see section “Dimethylformamide”). It can dissolve all compounds that would also dissolve in water. Orbital Technologies Corp. (Orbitec Inc.) of Madison, WI, has made a monopropellant consisting of 67.5 mass-% ADN and 32.5 mass-% formamide, and

a Swedish patent was filed for an ADN/formamide monopropellant. No other uses as a propellant ingredient are known.

## 2.2 Methylformamide

*N*-Methylformamide,  $\text{CH}_3\text{NHCHO}$ ,  $\text{C}_2\text{H}_5\text{NO}$ , monomethylformamide, MMF, NMF, CAS RN [2921-57-5] or [123-39-7], molecular mass: 59.0672 g/mol, is a colorless, nearly odorless liquid at room temperature. It is miscible with water in all proportions. NMF is mainly used as a reagent in various organic syntheses. It finds only limited applications as a highly polar solvent in comparison to the more frequently used dimethylformamide. The industrial or chemical laboratory uses of NMF are far fewer than those for either formamide or dimethylformamide (DMF). DMF is favored over NMF as a solvent due to its greater stability.

NMF has a density of  $1.011\text{ g/cm}^3$ , freezes at 269 K ( $-4^\circ\text{C} = 25^\circ\text{F}$ ), and boils at 455.7 K ( $182.6^\circ\text{C} = 360.6^\circ\text{F}$ ). The heat capacity is  $125.2\text{ J K}^{-1}\text{ mol}^{-1}$ . The heat of vaporization is  $56.2\text{ kJ/mol}$ .

Although the fuel component of the Swedish ADN-based monopropellant FLP-106 at first had not been identified by its inventors, all indications are that it is *N*-methylformamide. The enthalpy of formation of NMF could not be found in the literature, but the performance calculations in [1, 2] used a value of  $-258.2\text{ kJ/mol}$  which corresponds to  $-61.7\text{ kcal/mol}$ . Other sources [3] gave the enthalpy of formation of *N*-methylformamide as  $-4188\text{ J/g} = -247.4\text{ kJ/mol}$ . It is not known why the two numbers are so different and which is more accurate.

## 2.3 Dimethylformamide

Dimethylformamide, also known as *N,N*-dimethylformamide,  $(\text{CH}_3)_2\text{NCHO}$ ,  $\text{C}_3\text{H}_7\text{NO}$ , DMF, CAS RN [68-12-2], is a colorless liquid which is miscible with water and the majority of organic liquids in all proportions. DMF is a common non-aqueous solvent for chemical reactions because it can dissolve ionic as well as non-polar reactants and bring them into contact with each other. Pure dimethylformamide is odorless, whereas technical grade or degraded samples often have a fishy (mousy) smell due to an impurity of dimethylamine. Dimethylformamide is a polar (hydrophilic) aprotic solvent with a high boiling point. Dimethylformamide has a density of  $0.948\text{ g/cm}^3$ , freezes at 212.7 K ( $-60.5^\circ\text{C} = -76.8^\circ\text{F}$ ), and boils at 426 K ( $152$  to  $154^\circ\text{C}$ ). The refractive index  $n_D^{20}$  is 1.4305 and the viscosity is  $0.92\text{ mPa s}$  (at 293 K =  $20^\circ\text{C}$ ). The standard enthalpy of formation is  $-239.4 \pm 1.2\text{ kJ/mol}$ .

Dimethylformamide has not been used as a rocket fuel, but it has been used widely as a solvent in the synthesis of more energetic fuels, such as organic azides and glycidyl azide polymer (GAP). It may be present as a contaminant in those fuels stemming

from its use as a solvent, which is difficult to remove due to its low vapor pressure (516 Pa at 298 K). Dimethylformamide may be used as a solvent in the demilitarization of solid propellant rocket motors.

## 2.4 Azidoformamide

Azidoformamide,  $\text{N}_3\text{C}(=\text{NH})\text{NH}_2$ ,  $\text{CH}_3\text{N}_5$ , has been combined with several oxygen- and nitrogen-rich energetic acids to form azidoformamidinium salts. Azidoformamide is an isomer of aminotetrazole. When looking at the structure of azidoformamide,

one would guess that this compound should be called azidoformimide instead of azidoformamide, and that its salts should be called azidoformidinium instead of azidoformamidinium, because azidoformamide contains an imide  $>\text{C}=\text{NH}$  grouping instead of the  $>\text{C}=\text{O}$  group that is found in amides. The azidoformamidinium ion is resonance stabilized because the positive charge can reside on either of the two aminoimino nitrogens or on the carbon, giving a nearly symmetrical carbonium ion:

Azidoformamide itself, the free base, is not very stable. The salts are more stable than the free base from which they are derived. The decomposition of the azidoformamidinium ion proceeds via hydrogen azide and cyanamide, and ends up with ammonium cyanide, ammonium azide, and nitrogen.

### 2.4.1 Azidoformamidinium Nitrate

Azidoformamidinium nitrate can be obtained by reacting aminoguanidinium bicarbonate with sodium nitrite and nitric acid. Azidoformamidinium nitrate forms a double salt in 1:1 molar ratio with guanidinium nitrate [4].

### 2.4.2 Azidoformamidinium Perchlorate

The highly explosive azidoformamidinium perchlorate was obtained by the reaction of the hydrazine group of aminoguanidinium perchlorate with  $\text{HNO}_2$  formed from potassium nitrite in dilute aqueous perchloric acid solution [5]. After filtration of  $\text{KClO}_4$ , the

product was isolated simply by removing the solvent. The structure of the perchlorate salt in the crystalline state was determined using low-temperature single-crystal X-ray diffraction (XRD), indicating an orthorhombic structure. The crystallographic data of azidoformamidinium perchlorate are summarized in Table 22 (in Section 12.2 “Aminoguanidinium Perchlorate”). The crystals were very sensitive to impact or friction.

### 2.4.3 Azidoformamidinium Dinitramidate

The highly energetic isomers azidoformamidinium dinitramide and 5-aminotetrazolium dinitramide were synthesized by the reaction of potassium dinitramide and azidoformamidinium perchlorate or 5-aminotetrazolium perchlorate, respectively [6]. Both compounds have an oxygen balance of 0.0%, which means they are perfectly balanced to burn to nothing but CO<sub>2</sub> and H<sub>2</sub>O (besides N<sub>2</sub>).

The properties of bis(azidoformamidinium) 5,5'-azotetrazolate (AFZT) are listed in tables and illustrated in figures in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic and Heterocycloaliphatic Amines” under the section “Tetrazole Compounds.” Following its synthesis, AFZT had to be isolated and dried very rapidly after crystallization, as the product decomposed in solution [7]. AFZT dissolved in DMSO was completely decomposed within 10 min under formation of nitrogen. The controlled combustion of AFZT in a calorimeter takes place according to

### 2.4.4 Formamidinium Salts

Formamidinium nitroformate,  $[\text{NH}_2\text{CHNH}_2]^+[\text{C}(\text{NO}_2)_3]^-$ , was prepared by a simple metathetical reaction, the crystal structure was examined by XRD, nuclear magnetic resonance (NMR), and Raman and infrared (IR) spectroscopy, and the enthalpy of formation was predicted by computational chemistry [8]. All the nitroformate salts had higher predicted detonation pressures and velocities than trinitrotoluene (TNT). Formamidinium nitroformate was thermally less stable than 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX), but also less sensitive to friction and impact.

## 3 Urea

Urea, also known as carbamide, carbonyldiamide, (H<sub>2</sub>N)<sub>2</sub>CO, CH<sub>4</sub>N<sub>2</sub>O, CAS RN [57-13-6], is more widespread as a product of living beings' metabolism than as a rocket propellant ingredient. Urea can be formed by decomposition of ammonium cyanate or by reaction of liquid ammonia and liquid carbon dioxide under pressure (via ammonium carbonate and ammonium carbamate). Urea is used as a fertilizer and as a building block of polymers (urea-formaldehyde resins). Urea forms monovalent and divalent salts with strong acids. Some of those salts with oxidizing acids like nitric acid

or perchloric acid are potential explosives and propellant ingredients. Some chemists call the urea salts “uronium” salts, but this name is very uncommon.

Urea and urea nitrate

Urea has a density of 1.32 g/cm<sup>3</sup> and melts at 406–409 K (133–135 °C) with partial decomposition. Extended heating of molten urea results in loss of ammonia and the formation of biuret (see Section 4 “Biuret and Urea Derivatives”).

Mixtures of urea and ammonium nitrate used in the synthesis of nitroguanidine are potentially explosive even in aqueous solution.

Urea added to solid propellants can act as a coolant and would slow down the burning rate. It might also reduce the muzzle flash for gun propellants in barrel weapons. Urea is also able to act as a stabilizer for double-base propellants because it will effectively neutralize and destroy (scavenge) nitrous acid formed during storage and aging of nitrate ester-based propellants. However, its ethyl and phenyl derivatives are better suited to this task because they are liquids and more easily dispersed in the propellant blend than a solid. Urea has been added to emulsion explosives based on ammonium nitrate as a stabilizer to protect against the formation of free acids during storage and emplacement.

Alkyl- and aryl-substituted urea derivatives are widely used as stabilizers in nitrocellulose-based propellants because they can scavenge nitrous oxides and retard further decomposition of the propellant. The applications of alkyl- and aryl-substituted urea derivatives as stabilizers will be summarized in a future set on solid propellants.

*Diesel exhaust fluid* is an aqueous urea solution made with 32.5% high-purity urea and 67.5% deionized water and injected into the exhaust from diesel engines to reduce NO<sub>x</sub> emissions.

Urea that is to be used for propellants and explosives must meet purity requirements of MIL SPEC DOD-U-10866D (17 April 1979) Urea, Technical (Metric) or MIL-DTL-10866E Note 1 (Jul 2010).

### 3.1 Urea Nitrate

The most thoroughly investigated salt of urea is urea nitrate, [(NH<sub>2</sub>)<sub>2</sub>COH<sup>+</sup>][NO<sub>3</sub><sup>-</sup>], CH<sub>5</sub>N<sub>3</sub>O<sub>4</sub>, UN, CAS RN [124-47-0], which is also a potential explosive. Urea nitrate has been considered as a rocket propellant ingredient for low-flame-temperature propellants. Urea nitrate may also be called “uronium nitrate.” A common abbreviation is UN.

### 3.1.1 Preparation of Urea Nitrate

Urea nitrate can be prepared from urea and >95%  $\text{HNO}_3$  white fuming nitric acid in acetic acid as a solvent [9]. Acetic acid is a solvent for urea, but a non-solvent for urea nitrate.

It would be undesirable or even ill advised to have to heat a reacting mixture of incompletely dissolved urea and nitric acid to 378–408 K (105–135 °C) to achieve a uniform reaction mixture [10]. At those temperatures, incipient decomposition will spoil the product.

In industry, most of the UN made by one of these methods is subsequently used for making nitrourea.

Not for rocket propellant applications but for academic studies of crystal structure by the Weissenberg single-crystal XRD method, may it be desirable to grow large single crystals of urea nitrate. This is possible by evaporating a solution that contains UN in nitric acid solutions [11]. Large, perfect crystals of UN were obtained by the addition of concentrated nitric acid to an aqueous solution of the salt followed by spontaneous evaporation. The angles of the crystal faces were then measured in a goniometer. See also [12].

### 3.1.2 Physical Properties of Urea Nitrate

The physical properties of UN are summarized in Table 1. Table 2 gives a comparison of the physical properties of UN and nitrourea. Nitrourea can be made from UN.

**Table 1:** Physical properties of urea nitrate.

| Property                                 | SI units                   |             | Other units                   |                 | References |

Data source: [19]

The sublimation UN in a continuously pumped vacuum was measured using a thermogravimetric method in the temperature range 329–370 K (56–97 °C) and the enthalpy of sublimation was  $79 \pm 5.4$  kJ/mol [20]. There are four good reasons why the weight loss was exclusively due to sublimation: Firstly, 100% weight loss was possible (no residue). Secondly, the operating temperature was well below the lowest possible decomposition temperature of about 378 K (105 °C). Thirdly, a sample was placed in a glass tube and evacuated continuously with about one third of the tube being inserted in boiling water (367 K = 94 °C). The UN disappeared from the bottom of the sample cell and condensed on the cooler walls of the upper part of the sample cell which were kept at room temperature. The sublimate added up to about 95% of the initial sample weight, and on the basis of XRD and IR measurements, it was found to be pure urea nitrate. Fourthly, a sample was heated at 339 K (66 °C) under continuous vacuum in the thermogravimetric system and the residues after 8 and 69% weight loss were collected separately and analyzed by IR. The IR patterns of both of these residues were the same and matched exactly that of the original urea nitrate, showing that no decomposition had occurred.

The vapor pressure of UN was measured at 353–393 K (80–120 °C) using an isothermal thermogravimetric weight-loss method and compared to that of guanidinium nitrate and ammonium nitrate (AN) [16]. The Clapeyron equation for UN vapor pressure is

$$\ln P = 57.377 - 20131/T$$

where  $P$  is the pressure in Pa and  $T$  is the temperature in kelvin. For a temperature of 298 K, this equation gives a vapor pressure of  $3.94 \times 10^{-5}$  Pa =  $2.96 \times 10^{-7}$  mm Hg. From the slope of this equation, an enthalpy of sublimation was calculated as 167 kJ/mol.

Urea nitrate is hygroscopic; the mass gain at 298 K (25°) is +0.76% at 90% R.H. and +23.2% at 100% R.H. The IR spectrum of UN is shown in Figure 1 (from [21]). Nitrourea is formed by dehydration of UN. Figure 2 gives a comparison of the IR spectra of nitrourea (top) and urea nitrate (bottom).

**Figure 1:** Infrared spectrum of urea nitrate. (Reproduced and modified from [21].)

**Figure 2:** Comparison of the IR spectra of recrystallized nitrourea (top) and recrystallized urea nitrate (bottom). (Republished and modified from [19], with permission of ©2013 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

### 3.1.2.1 Crystal Structure of Urea Nitrate

The crystal structure of UN was determined by neutron diffraction [22]. Urea nitrate crystallizes in a monoclinic structure with symmetry  $P2_1/c$  and lattice parameters  $a = 9.5434(6)$ ,  $b = 8.2010(5)$ ,  $c = 7.4982(4)$  Å, and  $\beta = 124.246^\circ$ . The crystal structure shows a layer arrangement with all atoms approximately at  $z = 1/4$  or  $1/2$ . The acidic proton is on the carbonyl oxygen atom with an O—H distance of  $1.006(3)$  Å and forms a hydrogen bond to a nitrate oxygen atom with an O—H...O distance of  $2.596(2)$  Å. Four other hydrogen bonds of the type N—H...O join the uronium and nitrate ions into a two-dimensional network. The only forces between the layers are of the van der Waals type.

These results agree quite well with data obtained by XRD [15]. The space group of the crystal is  $P2_1/c$ . The cell dimensions and their standard deviations are  $a = 9.527 \pm 0.007$ ,  $b = 8.203 \pm 0.005$ , and  $c = 7.523 \pm 0.006$  Å;  $\beta = 124.37 \pm 0.05^\circ$ . With four molecules in the unit cell, the calculated XRD density is  $1.68 \text{ g/cm}^3$ . The pycnometric experimental value is  $1.69 \text{ g/cm}^3$ . See also [12, 23–25].

The electronic structure of UN has been calculated by the SCC-DV-Xa quantum chemical method and its IR and UV absorption bands and XPS binding energy were investigated [26].

An examination of UN crystals at pressures up to 26 GPa using Raman spectroscopy and XRD exhibited a supramolecular structure with the uronium cation and nitrate anion held together by multiple hydrogen bonds in the layer [27]. The irreversible phase transition in the range 9–15 GPa has been confirmed by experimental results and was proposed to stem from rearrangements of hydrogen bonds indicating a new phase.

### 3.1.3 Chemical Properties of Urea Nitrate

Urea nitrate as a propellant ingredient is slightly under-oxidized, but it has a good nitrogen content. The oxygen balance of UN is  $-6.5\%$  and the nitrogen content is  $34.14 \text{ mass-\% N}$ .

#### 3.1.3.1 Analysis and Detection of Urea Nitrate

In the wake of widespread use of UN in unauthorized production of clandestine explosives, a need has arisen to identify this chemical in luggage taken on airplanes and other modes of transportation. All methods of explosive detection have been tested for their sensitivity toward UN and other explosives likely to be found in or on the hands of terrorists.

This includes electrospray ionization mass spectrometry [28]. The structure of the ions was deduced using measurements of isotopically labeled UN. Urea nitrate was detected and identified in real-world criminal cases using this method.

A sensitive, specific, and simple spot plate color indicator test for UN is based on the formation of a red pigment upon the reaction between UN and *p*-di-

methylaminocinnamaldehyde (*p*-DMAC) under neutral conditions [29]. Urea itself did not give a red color with *p*-DMAC under the same conditions. Other potential sources of a false-positive response, e.g., common fertilizers, did not produce the red color with *p*-DMAC. Exhibits collected from ten terrorist cases were tested with *p*-DMAC. The results were in full agreement with those obtained by more sophisticated instrumental techniques including GC/MS, XRD, and IR.

It has already been mentioned that UN is a powerful improvised explosive sometimes used by terrorists. It is difficult to identify UN in post-explosion debris, since only a very small fraction survives the blast. Also, in the presence of water, it readily dissociates to its original components, i.e., urea and nitric acid. Post-blast debris of UN can be confused with ammonium nitrate, the main solid product of UN thermal decomposition. In a comprehensive study towards identification of UN in post-blast traces, a spectrophotometric technique for quantitative determination of UN was developed, and conditions were found for extraction and separation of unexploded surviving traces of urea nitrate [30].

In a similar effort, the residues were extracted with hot acetone, and the extract HPLC-chromatographed on Chromosorb [31]. The eluent was analyzed by LC/MS using atmospheric pressure chemical ionization (APCI). By applying this technique, it was possible to identify UN in actual exhibits from crime scenes.

### 3.1.3.2 Thermal Stability of Urea Nitrate

The kinetics of isothermal decomposition of UN, which melts with decomposition at 425 K (152 °C), was studied in open air in the temperature range 379–423 K (106–150 °C) by TGA [14]. GC analysis of product gases indicated the formation of CO<sub>2</sub>, N<sub>2</sub>O, and traces of water vapor as product gases. A pasty amorphous residue was found to be cyanourea based on wet chemical and infrared analysis. The reaction for decomposition of UN in open air is most likely

The weight loss–time curve exhibited an acceleratory region extending almost to the end of the main reaction (35% decomposition) and followed a third-order nucleation model obeying the relation

$$\alpha^{\frac{1}{3}} = K(t - t_0)$$

where  $\alpha$  = fraction of sample reacted at time  $t$ ,  $K$  = reaction rate constant, and  $t_0$  = induction time with an enthalpy of activation of  $H_a = 27.6 \pm 1.2$  kcal/mol. The rate of decomposition was slightly accelerated in He atmosphere and slightly retarded in N<sub>2</sub>O and CO<sub>2</sub> atmospheres, while water vapor drastically reduced the rate. Urea nitrate thermogravimetric analysis (TGA) and differential thermal analysis (DTA) were carried out both in air and under an atmosphere of nitrogen using 5-mg samples at a linear heating rate of 10 °C/min [32]. Urea nitrate started to decompose at 398 K (125 °C) and there was a break in the weight loss curve at 428 K (155 °C), showing about 40% weight

loss. The decomposition was rapid up to 548 K (275 °C) and about 95% of the initial mass volatilized by the time the sample reached 548 K (275 °C). No residue remained at 598 K (325 °C). In a separate test, a known amount of UN was heated and kept at 413 K (140 °C) and the residue obtained was examined. The weight loss observed was 35%, corresponding to the calculated weight loss of 35% for the anticipated formation of  $\text{NH}_4\text{NO}_3$  from urea nitrate. The IR spectrum of the residue resembled that of  $\text{NH}_4\text{NO}_3$ . The DTA showed three exothermic peaks at 428, 448, and 558 K (155, 175, and 285 °C) and an endotherm at 433 K (160 °C). The initial exotherm was attributed to the expulsion of  $\text{HOCN}$  and was more pronounced in air than in nitrogen. In the mass spectrum there was no molecular peak corresponding to urea nitrate,  $m/e$  123, and there were no mass peaks above  $m/e$  61,  $[(\text{CH}_2\text{N})_2\text{COH}]^+$ . The major fragments were  $\text{NO}$ ,  $\text{N}_2\text{O}$ , and  $\text{NO}_2$  derived primarily from nitrate, and  $\text{H}_2\text{NCN}$ ,  $\text{HNCO}$ ,  $\text{NCO}$ , and  $\text{OC}(\text{NH}_2)$  fragments obtained from the cation moiety. On a hot plate with rapid heating, the deflagration point was 459 K (186 °C = 367 °F). See also [23, 33].

The initial steps in the decomposition process of UN were studied by using *ab initio* calculations [34]. To determine the most favorable reaction pathway of decomposition, geometries, structures, and energies were evaluated for reactants, products, intermediates, and transition states of the proposed pathways. It was found that there is a reaction path for the endothermic channel with a potential energy barrier of 47.8 kcal/mol. Although a considerable difference was found between the actual crystal structure and the optimized structure of UN, these results strongly suggested that decomposition occurs via internal hydrogen transfer from one amino group to the other  $-\text{NH}_2$  group to produce  $\text{NH}_3$ . These calculated results seem to support the experimental results observed during the thermal decomposition of UN by using T-jump/Fourier-transform IR spectroscopy (FTIR).

Electronic structure calculations were performed to investigate the initial steps in the gas-phase decomposition of urea and urea nitrate [35]. Gaseous UN formed by the association of urea and  $\text{HNO}_3$  has two isomeric forms, both of which are acid–base complexes stabilized by the hydrogen bonding interactions involving the acidic proton of  $\text{HNO}_3$  and either the O or N atoms of urea, with binding energies of 13.7 and 8.3 kcal/mol, respectively, and with estimated standard enthalpies of formation ( $\Delta H_f^{298}$ ) of  $-102.3$  and  $-97.1$  kcal/mol, respectively. Both isomers can undergo relatively facile double proton transfer within cyclic hydrogen-bonded structures. In both cases,  $\text{HNO}_3$  plays a catalytic role for the (1,3) H-shifts in urea by acting as a donor of the first and an acceptor of the second proton transferred in a relay fashion. The  $\text{HNO}_3$ -catalyzed breakdown of urea to  $\text{HNCO}$  and  $\text{NH}_3$  is predicted to be the most favorable decomposition pathway for gaseous UN. Thus,  $\text{HNCO} + \text{NH}_3 + \text{HNO}_3$  and their association products (e.g., ammonium nitrate and isocyanate) are expected to be the major initial products of UN decomposition. This is consistent with experimental T-jump/FTIR data [33].

The decomposition of UN has been determined with isothermal heating followed by quantification of both remaining nitrate and remaining base [36]. Activation ener-

gies determined for urea for nitrate and urea itself were 158 and 131 kJ/mol, with the pre-exponential factors being  $1.39 \times 10^{12} \text{ s}^{-1}$  and  $2.66 \times 10^9 \text{ s}^{-1}$ , respectively. These pairs of Arrhenius constants predict decomposition rates less than a factor of two apart. Literature values for ammonium nitrate decomposition indicate that it should decompose somewhat slower than UN and faster than guanidinium nitrate. Differential scanning calorimetry (DSC) also indicated this ordering but suggested that UN is substantially less stable than was observed in the isothermal experiments. The thermal stability of guanidinium nitrate was measured as part of the same study. A DSC thermogram of UN sealed in glass capillary tubes heated at a rate of  $20^\circ\text{C}/\text{min}$  is shown in Figure 3.

**Figure 3:** Thermogram of urea nitrate in a glass capillary tube. (Republished and modified from [36], with permission of ©2009 Taylor & Francis, [www.tandfonline.com](http://www.tandfonline.com).)

The decomposition of UN at high temperatures was studied using adiabatic and non-isothermal calorimetry techniques [13]. Gas species released were identified and quantified *in situ* using TGA-IR spectroscopy/MS. A decomposition mechanism at high temperature was proposed based on the nature and sequences of gaseous species observed. Non-isothermal decomposition kinetics of UN were measured using preset constant heating rates to give activation energies of  $E_a = 206$  and  $113 \text{ kJ/mol}$  with pre-exponential factors  $\ln Z = 47$  and  $21 \text{ min}^{-1}$ , in a closed and open system, respectively. In these systems the major UN decomposition step is strongly coupled to an endothermic dissociation reaction. Species remaining after this exothermic decomposition showed only minor exothermicity at higher temperatures. This is contrasted with the onset of

adiabatic decomposition, which occurred  $\sim 30^\circ\text{C}$  below the apparent melting point of 428–429 K (155–156  $^\circ\text{C}$ ).

In a parallel study, when studying the aging and slow degradation of UN at temperatures below the melting point at 373 K (100  $^\circ\text{C}$ ) by using thermal analysis and spectroscopic methods including IR, Raman,  $^1\text{H}$ , and  $^{13}\text{C}$  NMR techniques, it was found that UN was completely degraded after 72 h at 100  $^\circ\text{C}$  into a mixture of solids (69%) and released gaseous species (31%) [37]. The remaining solid mixture was composed of ammonium nitrate, urea, and biuret, while unreacted residual nitric and isocyanic acids as well as traces of ammonia were released as gaseous species at 373 K (100  $^\circ\text{C}$ ). The thermal stability of UN under less extreme storage conditions (323 K = 50  $^\circ\text{C}$ ) was also examined by isothermal nano-calorimetry.

In a repeat of an earlier study, the thermogram of UN showed a melt endotherm near 435 K = 162  $^\circ\text{C}$  and a sharp exotherm immediately thereafter at 440 K = 167  $^\circ\text{C}$  [19]. A secondary broader exotherm was observed around 653 K = 380  $^\circ\text{C}$  (Figure 4). The thermogram on the right is the same initial event shown at different scale expansions, revealing a shoulder before the exotherm gets into full swing. The decomposition of UN leads to a mixture of ammonium isocyanate, biuret, melamine, cyanourea, and cyanuric acid.

**Figure 4:** DSC thermograms of urea nitrate decomposition, scan rate 10 K/min (Republished and modified from [19], with permission of ©2013 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

In the 373 K (100  $^\circ\text{C}$ ) thermal stability heat test, no acid and no explosion were observed within 300 min. In the 408 K (135  $^\circ\text{C}$ ) heat test, some acid was detected within 30 min, but no explosion occurred within 300 min.

### 3.1.3.3 Thermal Stability of Urea Nitrate/Metal Complexes

The thermal stability of the Fe and Cr complex nitrates of urea was investigated by DTA and TGA [38]. The coordination of urea to a metal ligand sphere increased its thermal stability. The thermal stability of the Cr complex was greater than that of Fe complex. The Fe complex decomposed not to  $\text{Fe}_2\text{O}_3$  but to  $\text{Fe}(\text{NO}_3)_2$ , while the Cr complex decomposed to  $\text{Cr}_2\text{O}_3$  during the isothermal decomposition over the temperature range of 433 to 493 K (160 to 220 °C). A first-order equation can best describe the decomposition reaction for both complexes. The activation energies were 160.4 kJ/mol for the Fe complex and 174.0 kJ/mol for the Cr complex. It was suggested that the nitrate ions in the Fe nitrate complex participated only partially in the reaction.

### 3.1.4 Safety Properties of Urea Nitrate

Urea nitrate is known as an explosive material, but not commercially used as such. The friction sensitivity and the shock sensitivity were low [39]. The critical shock initiation pressure of UN (bulk density  $0.68 \text{ g/cm}^3$ ) was measured in a card gap test and shown to be 2.2–2.6 GPa.

In the Bundesanstalt für Materialforschung und -prüfung (BAM) impact test apparatus, no reaction was noted at impact energies up to 49 Nm. Likewise, in the BAM friction sensitivity test apparatus, no reaction was noted at pistil loads up to 353 N.

In the Picatinny friction sensitivity apparatus, loads of up to 36 kp = 353 N pistil load gave no reaction. In the Picatinny impact sensitivity apparatus, impacts of up to  $5 \text{ kp} \cdot \text{m} = 49 \text{ Nm}$  gave no reaction [17].

### 3.1.5 Explosive Performance of Urea Nitrate

Detonation velocities of UN were measured in various cylindrical containers with composition C-4 as a booster. It was shown that the detonation velocity of UN is typical for a steady-state detonation. Detonation velocities of samples confined in a steel tube could reach 5000 m/s [39]. The effects of bulk density, charge diameter, and degree of confinement on detonation velocity were studied.

Other sources give the detonation velocity as 3400 m/s at a packing density of  $0.85 \text{ g/cm}^3$  in a 30-mm diameter paper tube when driven by 1.5 g of mercury fulminate, and 4700 m/s at a packing density of  $1.20 \text{ g/cm}^3$  in a 30-mm diameter steel tube when initiated by 1.5 g of mercury fulminate [17].

In the lead block test, the explosion of UN will increase the cavity volume by  $270 \text{ cm}^3/10 \text{ g}$ . See also [40].

### 3.1.6 Other Applications for Urea Nitrate

Because both urea and nitrate ion are good sources of nitrogen in fertilizers, urea nitrate in the dry state would make a good fertilizer. However, for safety reasons, it would have to be diluted substantially with inert materials (limestone, dolomite) to desensitize the pure compound. Aqueous solutions of urea nitrate and ammonium nitrate with 28–32% usable nitrogen are widely used as fertilizers. There is concern that urea nitrate may form inadvertently in fertilizer mixtures containing both urea and ammonium nitrate. Such mixtures may be detonable.

## 3.2 Urea Perchlorate

Urea perchlorate,  $\text{H}_2\text{NCONH}_3\text{ClO}_4$ ,  $\text{CH}_5\text{N}_2\text{O}_5\text{Cl}$ , CAS RN [1872-07-6], forms colorless, very hygroscopic crystals that explode upon ignition without burning. The oxygen balance for complete combustion to  $\text{CO}_2$  is positive +4.98%. The nitrogen content is 17.46% N. Urea perchlorate may be useful as an explosive, but it is too sensitive to be used as a rocket propellant.

Urea perchlorate melts at 356 K (83 °C) and starts decomposing at 413 K (160 °C). It is quite soluble in water: at 293 K (20 °C), 958 g urea perchlorate will dissolve in 100 g water and the density of the saturated aqueous solution at 293 K (20 °C) is 1.6226 g/cm<sup>3</sup>. The impact sensitivity of the saturated solution was six negatives (no fires) out of six tests with a 5-kg hammer dropped from 60 cm.

### 3.2.1 Detonability of Urea Perchlorate Solutions

Numerous patents have been issued for the use of urea perchlorate solutions in combination with organic fuels as liquid explosives [41, 42]. The detonability of aqueous solutions/suspensions of organic amine perchlorates was studied in steel and glass ampules with an electric detonator with or without an intermediate hexogen booster. The isochoric detonation temperature of aqueous solutions of urea perchlorate was 1700–1740 K, and the upper concentration limit of  $\text{H}_2\text{O}$  below which the solutions retained their detonation capacity was 22–23%  $\text{H}_2\text{O}$  [43]. In a 28-mm I.D. steel tube with a tetryl booster, no stable reaction wave was observed in this solution.

## 3.3 Urea Dinitramide

Urea dinitramide,  $[\text{H}_2\text{NCONH}_3^+][\text{N}_3\text{O}_4^-]$ ,  $\text{CH}_5\text{N}_5\text{O}_5$ , melts at 371–373 K (98–100 °C) [44].

## 4 Biuret and Urea Derivatives

Biuret, imidodicarbonic diamide, 2-imidodicarbonic diamide, carbamylurea,  $\text{H}_2\text{NCO-NHCONH}_2$ ,  $\text{C}_2\text{H}_5\text{N}_3\text{O}_2$ , molecular mass: 103.08 g/mol, CAS RN [108-19-0], is formed when urea is heated and one mol of ammonia is split off.

Biuret is a crystalline solid similar to urea. The enthalpy of formation is  $\Delta H_f^{298}(\text{S}) = -563.7 \pm 2.1 \text{ kJ/mol}$ . Biuret itself has not been used as a propellant ingredient, but several high-energy compounds are based on biuret.

### 4.1 Dinitrobiuret

Dinitrobiuret, also known as 1,5-dinitrobiuret; 1-nitro-3-(nitrocarbamoyl)urea, imidodicarbonic diamide, *N,N'*-dinitro-; *N,N*-dinitrodicarbonimidic diamide,  $\text{O}_2\text{NNHCONH-CONHNO}_2$ ,  $\text{C}_2\text{H}_3\text{N}_5\text{O}_6$ , DNB, CAS RN [671181-09-2], is a very powerful energetic additive and relatively easy to obtain. DNB has an approximate planar structure (Figure 5).

Figure 5: Molecular structure of dinitrobiuret.

The standard enthalpy of formation ( $\Delta H_f$ ) was calculated from quantum mechanical considerations to be  $-353 \text{ kJ/mol}$  ( $-1829 \text{ kJ/kg}$ ). The enthalpy ( $\Delta H_r$ ) for the reaction of DNB(s)

was determined to be  $1003 \pm 39 \text{ kJ/mol}$  ( $5195 \pm 200 \text{ kJ/kg}$ ) using bomb calorimetry. DNB detonated strongly in the steel sleeve test, without the need of adding any additional oxidizer. The detonation velocity and detonation pressure were calculated to be  $8.66 \text{ mm/s}$  and  $33.9 \text{ GPa}$ , respectively.

The calculated theoretical enthalpy of formation of dinitrobiuret is  $-353 \text{ kJ/mol} = -1829 \text{ kJ/kg}$  [45–47]. Dinitrobiuret has a slightly positive oxygen balance of  $+4.1\%$ . The predicted detonation velocity and detonation pressure of DNB was calculated using the empirical equations by Kamlet and Jacobs and obtained as  $D = 8.66 \text{ mm}/\mu\text{s}$ ,

$P = 33.9$  GPa. Other data reported for the heat of combustion of dinitrobiuret are 851 kJ/mol (203.3 kcal/mol) [48].

The thermal decomposition of mononitrobiuret (MNB) and 1,5-dinitrobiuret was investigated by TGA and DSC and the gaseous decomposition products were identified by mass spectrometry (MS) and IR [49]. Decomposition appeared in both cases to be initiated by the release of nitramine. The gaseous products after the exothermic decomposition were similar for MNB and DNB. The decomposition of MNB leads to the formation of urea, biuret, triuret, tetrauret, and cyanuric acid.

Computer simulations were performed for decomposition of 1,5-dinitrobiuret over a temperature range from 4000 to 6000 K, aimed at providing insight into decomposition mechanisms [50]. The trajectories revealed various decomposition paths and reproduced the products (including HNCO,  $N_2O$ ,  $NO_2$ , NO, and  $H_2O$ ) observed in pyrolysis experiments. Decomposition starts with elimination of  $NO_2$  from DNB, followed by consecutive elimination of two isocyanic acid (HNCO) molecules from the derivative intermediate. According to computer predictions of the weakest link, the dominant initial decomposition path corresponds to elimination of  $HNNO_2H$  via a concerted mechanism where the molecular decomposition is accompanied with intra-molecular H-atom transfer from the central nitrogen to the terminal nitro oxygen. Other important paths correspond to elimination of  $NO_2$  and  $H_2NNO_2$ .  $NO_2$  elimination is a simple N–N bond scission process.

The combustion dynamics of 1,5-dinitrobiuret with nitric acid have been examined by computer methods using reactive molecular dynamics simulations [51]. The simulations showed that at certain compositions of the mixture, reaction kinetics result in a very sharp release of thermal energy, which can be associated with spontaneous ignition or hypergolicity.

Calculations showed that the pseudo-*trans* conformer of 1,5-dinitrobiuret is the most stable form of the isolated molecule, while the pseudo-*cis* conformer is about 7.5 kJ/mol higher in energy [52]. The structure of gaseous 1,5-dinitrobiuret is different from that in the crystal state, where the molecules have pseudo-*cis* conformation. The value of enthalpy of formation of gaseous 1,5-dinitrobiuret ( $-257 \pm 5$  kJ/mol) was calculated from isodesmic reactions. Combining this value with the empirically estimated enthalpy of sublimation, the enthalpy of formation of crystalline 1,5-dinitrobiuret was predicted to be  $-415 \pm 15$  kJ/mol. The energy of the weakest N– $NO_2$  bond was 190–200 kJ/mol.

It had been proposed that an important step for the hypergolic ignition of ionic liquid bipropellants composed of nitric acid and dicyanamide salts is the activation and dissociation of the 1,5-dinitrobiuret anion formed from dicyanamide [53].

A quasi-classical direct dynamics simulation computation was supposed to explain the intermediates formed in the hypergolic ignition reaction [54–56].

Mononitrobiuret (MNB) and 1,5-dinitrobiuret (DNB) are tetrazole-free, nitrogen-rich energetic compounds. A comprehensive *ab initio* kinetics study on the thermal decomposition mechanisms of MNB and DNB has been carried out [57].

## 4.2 Nitroalkylurea Derivatives

Bis(2,2,2-trinitroethyl)urea, also known as di(2,2,2-trinitroethyl)urea, BTNEU,  $C_5H_6N_8O_{13}$ , is one of the few explosives that is exactly stoichiometric oxygen balanced (oxygen balance:  $\pm 0\%$ ) for combustion to carbon dioxide and water. It has a nitrogen content of 29.02 mass-% N.

It has a molecular mass of 386.15 g/mol and an enthalpy of formation of  $-199.2 \text{ kcal/kg} = -833.2 \text{ kJ/kg} = -321.7 \text{ kJ/mol} = -76.9 \text{ kcal/mol}$ .

## 5 Carbamic Acid Derivatives

Carbamic acid,  $H_2N-COOH$ , CAS RN [463-77-4] itself is not stable, but many of its salts have been prepared and some have been evaluated as propellant ingredients. It is a zwitter between an amide and a carboxylic acid. Carbamic acid is an intermediate in the production of urea, which involves the reaction of carbon dioxide and ammonia. The gross formula of carbamic acid,  $CH_3NO_2$ , is the same as that of nitromethane, but the compound is much less energetic than nitromethane, due to the fact that the oxygens are attached to carbon and not to nitrogen. Carbamate linkages can be found in insecticides, polymers, and some metabolic intermediates. The medicinal use of ethyl carbamate (urethane) was discontinued after ethyl carbamate was identified as a carcinogen. The widespread presence of ethyl carbamate in alcoholic beverages and fermented food was first discovered during the mid-1980s and continues to be a matter of concern.

Ammonium carbamate can hydrolyze to ammonium carbonate or dissociate reversibly to ammonia and carbon dioxide. When heated in a pressure autoclave it converts irreversibly to urea and water, which is an industrial process for making urea. Ammonium carbamate has been used as a subliming solid in low-thrust rocket engines.

The reaction of alcohols with chlorosulfonyl isocyanate forms alkyl carbamates which can be nitrated with mixed acid to form energetic nitrocarbamates [58]. Polyols like pentaerythritol can be converted to a tetracarbamate and nitrated to give pentaerythritol tetranitrocarbamate, [3-(nitrocarbamoyloxy)-2,2-bis(nitrocarbamoyloxymethyl)propyl]-*N*-nitrocarbamate

The density of pentaerythritol tetranitrocarbamate is  $1.77 \text{ g/cm}^3$  at 100 K ( $-173^\circ\text{C}$ ). It did not melt, but started to decompose at 469 K ( $196^\circ\text{C}$ ) which is 30 degrees better than pentaerythritol tetranitrate (PETN). The enthalpy of formation is  $-1311 \text{ kJ/mol}$ .

The reaction of urea with trinitromethane and acetaldehyde forms *N,N'*-bis(1,1,1-trinitroprop-2-yl)urea which can be converted to 1,1,1-trinitroprop-2-yl carbamate and 1,1,1-trinitroprop-2-yl nitrocarbamate which can be used as energetic additives or explosives [59].

2,2,2-Trinitroethyl carbamate was obtained by the reaction of 2,2,2-trinitroethyl chloroformate with aqueous ammonia. The nitration of 2,2,2-trinitroethyl carbamate with anhydrous nitric acid and sulfuric acid yielded 2,2,2-trinitroethyl nitrocarbamate, which has potential as a perchlorate-free highly energetic dense oxidizer with a high oxygen balance of  $\Omega(\text{CO}_2) = +14.9\%$  [60]. The thermal stability was studied using DSC and the energies of formation and detonation parameters were calculated.

## 5.1 Azodicarbonamide and Hydrazodicarbonamide

### 5.1.1 Azodicarbonamide

Azodicarbonamide, also known as azobisformamide, 1,1'-azobisformamide, 1,2-diazenedicarboxamide, azodicarbonic acid diamide, carbamoyliminurea,  $\text{C}_2\text{H}_4\text{N}_4\text{O}_2$ , CAS RN [123-77-3],

is produced in tonnage quantities and used widely as a blowing agent for foamed plastics. It can be used as a coolant and source of nitrogen in rocket propellants, gun pro-

pellants, and solid gas generant formulations. Solid gas generant formulations containing azodicarbonamide will be discussed in future volumes on solid propellants and gas generants as part of the *Encyclopedia of Rocket Propellants*.

Azodicarbonamide is manufactured by the reaction of dihydrazinium sulfate and urea at high temperature and under pressure. The product of this reaction is then oxidized using sodium chlorate or free chlorine and centrifuged to yield a slurry containing azodicarbonamide. The slurry is washed to remove impurities and dried to obtain the azodicarbonamide powder. This is then pulverized before packaging. It can also be produced by electrochemical oxidation [61]. Azodicarbonamide that is labeled with the radioisotope  $^{14}\text{C}$  for metabolic fate and toxicity studies can be made by reaction of hydrazinium sulfate with potassium [ $^{14}\text{C}$ ]cyanate, followed by oxidation of the resulting biurea [62].

Azodicarbonamide is a light yellow to orange powder with a decomposition temperature of 477–481 K (204–208 °C = 400–410 °F), depending on the rate of heating. It is available in various particle size ranges down to 3.5  $\mu\text{m}$  for applications as a foaming agent in the plastics industry. It is poorly soluble in water at room temperature (50 mg/L), although it is slightly soluble in hot water. The standard enthalpy of formation of azodicarbonamide is  $-292\text{ kJ/mol}$  ( $-69.91\text{ kcal/mol}$ ) [63].

There have been several deflagrations in azodicarbonamide storage warehouses when the material was improperly stored in oversize containers.

Azodicarbonamide is used as a flour-bleaching agent and a bread dough conditioner, speeding up the bread making process in a bread factory. Azodicarbonamide reacts with moist flour as an oxidizing agent. The main reaction product is biurea, a derivative of urea, which is stable during baking. Secondary reaction products include semicarbazide and ethyl carbamate. Both of those are potentially toxic and one seriously wonders how this chemical is allowed to be in bread and eaten by the entire population at large. Azodicarbonamide is not authorized for use as a food additive in Australia and the European Union, so why is it safe to use it in the United States? In the United States, azodicarbonamide has a Generally Recognized As Safe (GRAS) status and is allowed to be added to flour at levels up to 45 ppm [64].

### 5.1.2 Hydrazodicarbonamide

Hydrazodicarbonamide, also known as carbamoylaminourea, ureidourea, 1,2-hydrazinedicarboxamide,  $\text{C}_2\text{H}_6\text{N}_4\text{O}_2$ , CAS RN [110-21-4],

melts at 521 K (248 °C) and the standard enthalpy of formation of hydrazodicarbonamide is  $-499\text{ kJ/mol}$  ( $-119.19\text{ kcal/mol}$ ; [63]).

Hydrazodicarbonamide can be prepared by reaction of urea and hydrazine in an acidic medium [65]. It is an intermediate in the preparation of azodicarbonamide. Hydrazodicarbonamide would be a good coolant and ingredient for gas generants, but there are no known applications and it is not produced in as large quantities as azodicarbonamide. Numerous patent applications list hydrazodicarbonamide along with azodicarbonamide as a gas generant ingredient.

## 6 Semicarbazide

Semicarbazide,  $\text{H}_2\text{NNHCONH}_2$ ,  $\text{CH}_5\text{N}_3\text{O}$ , CAS RN [57-56-7] is a white crystalline powder that is widely used as a metal ion-complexing reagent in analytical chemistry. It forms stable complexes with most transition metals. Semicarbazide melts at 369 K (96 °C) and has a density of  $1.484 \text{ g/cm}^3$ . It is soluble in water and somewhat soluble in ethanol.

Semicarbazide forms a nitrate salt with nitric acid. The dry nitrate salt melts at 396 K (123 °C) with decomposition. Semicarbazide also forms a perchlorate salt with perchloric acid. The dry perchlorate salt melts at 551 K (278 °C) with explosion.

Semicarbazide chloride has been suggested as a burning rate suppressant, but there are no known actual uses of any of these salts.

## 7 Carbohydrazide

Carbohydrazide, also known as *N,N'*-diaminourea,  $\text{H}_2\text{NNHCONHNH}_2$ ,  $\text{C}_1\text{H}_6\text{N}_4\text{O}_1$ , CHZ, CAS RN [479-18-7], has a higher nitrogen content than urea and makes a good coolant for gas generants. Carbohydrazide can be used as an oxygen scavenger in boiler-feed water treatment for power plants. In those applications, it is a non-volatile alternative to volatile hydrazine hydrate. At high temperatures such as those in a boiler, carbohydrazide reacts with oxygen to form water, nitrogen, and urea.

### 7.1 Preparation of Carbohydrazide

Carbohydrazide can be prepared by hydrazinolysis of dimethyl carbonate or ethylcarbazate with hydrazine hydrate in aqueous solution [66].

### 7.2 Physical Properties of Carbohydrazide

Carbohydrazide melts at 425–427 K (152–154 °C) and has a density of  $1.616 \text{ g/cm}^3$  at 293 K (20 °C).

The molecular structures of gaseous isomers and the crystalline state of carbohydrazide were examined by quantum mechanical methods [67]. Three stable isomers were located on the energy potential curve. The structure in the crystal is the most stable one. The vibrational frequencies were predicted and agreed well with the experimental data.

### 7.3 Chemical Properties of Carbohydrazide

Carbohydrazide is a weak base and forms monobasic and dibasic salts with strong acids. The salts may be called diaminouronium salts, but this is a very uncommon name. The salts with oxidizing inorganic acids are of interest as propellant ingredients. Carbohydrazide metal complexes were proposed as gas generants for automobile air bag inflators, such as the carbohydrazide Mg complex [68, 69] or Cd perchlorate complexes [70].

Carbohydrazide forms complexes (similar to semicarbazide) with many metal ions. These metal ions can catalyze the combustion of carbohydrazide in the presence of suitable oxidizers, leading to nitrogen-rich gases suitable for inflation of automobile-occupant restraint systems.

The specific heat capacities of four carbohydrazide nitrate energetic coordination compounds  $[M(CHZ)_3](NO_3)_2$ , ( $M = Mn, Co, Zn, Ni$ ) were determined by DSC and curve-fit regression equations for the specific heat capacity as a function of temperature were obtained [71]. For all except  $Zn(CHZ)_3(NO_3)_2$ , the specific heat capacity of the compounds changed substantially, and one or more peaks appeared in the curves of the specific heat capacity. In TGA at 473 K (200 °C), only  $Co(CHZ)_3(NO_3)_2$  lost 8.6% of its mass. FTIR spectra were not the same at different temperatures; therefore, it is possible that polymorphic crystal transformations resulted in the changes of specific heat capacities.

#### 7.3.1 Carbohydrazide Salts

Carbohydrazide(1+) nitrate, diaminouronium(1+) nitrate, an energetic salt, was compared with EDDN and ethylenediamine diperchlorate (EDDP) and in a study on the effect of the molecular structure of energetic materials on the burning rate [72]. With an excess of strong nitric acid, carbohydrazide can also form carbohydrazidium(2+) dinitrate [73].

Carbohydrazidium(2+) dinitrate crystallized with one molecule of water as hydrate [74]. This salt is completely insensitive towards impact and friction, but, unfortunately, when heated it already decomposes at 388 K (115 °C).

Diaminouronium nitrate, diaminouronium dinitrate monohydrate, and diaminouronium perchlorate were synthesized by acidification of carbohydrazide [75]. The bis-perchlorate salt could not be isolated due to its high hygroscopicity.

The salts were fully characterized using XRD, NMR, and IR spectroscopy, MS, DSC, and elemental analysis. The sensitivities towards impact were 9J, 40J, and 2J, respectively. The sensitivities towards friction were 288 N, 360 N, and 5 N, respectively (BAM methods).

## 8 Nitrourea and Dinitrourea

### 8.1 Nitrourea

Nitrourea,  $\text{CH}_3\text{N}_3\text{O}_3$ , CAS RN [556-89-8], is a crystalline, colorless solid.

Nitrourea must not be confused with urea nitrate. Both substances form similar-looking, clear, colorless crystals, and are potentially explosive and can be converted into each other by dehydration or hydrolysis. If sufficiently desensitized and diluted, nitrourea could possibly be used as a propellant ingredient, but no applications are known.

#### 8.1.1 Preparation of Nitrourea

Nitrourea can be synthesized by dehydration of urea nitrate with sulfuric acid or acetic anhydride and acetic acid at 333 K (60 °C). It can be recrystallized from glacial acetic acid.

#### 8.1.2 Physical Properties of Nitrourea

The physical properties of nitrourea are summarized in Table 2 (“Physical Properties of Urea Nitrate” in the “Urea Nitrate” section) and here in Table 3. Other data reported for the heat of combustion of nitrourea are 553 kJ/mol (132.3 kcal/mol) [48].

The IR spectrum of nitrourea was already shown in Figure 2 in comparison to the spectrum of urea nitrate. Both urea nitrate and nitrourea have absorption bands around  $1700\text{ cm}^{-1}$  ( $\text{C}=\text{O}$ ) and in the high and low end of  $1300\text{ cm}^{-1}$  (NO), but urea nitrate is clearly distinguished by the broad band around  $2400\text{ cm}^{-1}$ . Nitrourea differs from urea nitrate between  $3400$  and  $2765\text{ cm}^{-1}$ , where at least five bands are resolved. Raman spectra of urea, urea nitrate, nitrourea, and AN are given in [19]. A similar IR spectrum and also a UV spectrum of nitrourea is shown in [76].

A theoretical analysis of the molecular structure of nitrourea and its possible tautomers was performed using Hartree–Fock and density functional theory (DFT), re-

**Table 3:** Physical properties of nitrourea.

| Property              | SI units                       |             | Other units       |              | References |

sulting in optimized geometries, vibrational frequencies, and some thermodynamic values in their ground states [77].

Computational modeling of the structures and properties of a series of nitro-substituted urea derivatives indicated that nitrated urea molecules have specific enthalpies of decomposition commensurate with current high-energy materials [78].

### 8.1.3 Chemical Properties of Nitrourea

Nitrourea has an only slightly negative oxygen balance of −7.6% and contains 39.95 mass-% nitrogen. It is a powerful explosive and potentially suitable as a propellant ingredient. Nitrourea is soluble and stable in benzene, diethyl ether, or chloroform, but it reacts with water. The solubility of nitrourea in water is 20 mg/mL. It tends to decompose spontaneously with moisture. *N*-Substituted-*N*-nitroureas are more hydrolytically stable. Dinitrourea also is very sensitive to hydrolysis.

When heated on a hot-stage microscope, nitrourea decomposed without melting and no solid residue remained, but in the DSC pan, a small amount of black residue was formed. In the DSC, a single sharp exotherm for nitrourea was observed at about 435 K (162 °C; Figure 6). The figure to the right shows the same event with different scale expansions. While the DSC of urea nitrate showed an endothermic melt, the nitrourea did not. The nitrourea energy released, according to DSC, was about double the energy of urea nitrate (1100 vs. 480 J/g).

### 8.1.4 Safety Properties of Nitrourea

In the Picatinny drop-weight sensitivity test apparatus with a 2-kg mass, only incomplete ignition occurred at 18 in (for comparison: 50% point for TNT is at 16 in). In the lead block test, the cavity was expanded by 310 cm<sup>3</sup>, which is 94% of the expansion typical for picric acid.

**Figure 6:** DSC Thermograms of nitrourea, scan rate 10 K/min. (Republished and modified from [19], with permission of ©2013 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

## 8.2 Dinitrourea

Dinitrourea, also known as 1,3-dinitrourea, *N,N'*-dinitrourea,  $\text{O}_2\text{NNHCONHNO}_2$ ,  $\text{CH}_2\text{N}_4\text{O}_5$ , DNU, CAS RN [176501-96-5], is a useful precursor in the synthesis of aliphatic and cyclic nitramine energetic compounds. It can also be used to prepare the parent compound, nitramide  $\text{H}_2\text{NNO}_2$ . An excellent summary review with 40 references of the synthesis, properties, structure, and reactions of *N,N'*-dinitrourea was published in 2013 [79].

### 8.2.1 Preparation of Dinitrourea

Dinitrourea can be prepared by stepwise nitration of urea with 100%  $\text{HNO}_3$ /20% oleum via mononitrourea as an intermediate. DNU was obtained in 95% yield via direct nitration of urea with a mixture of equal parts of 98%  $\text{HNO}_3$  and 20% oleum [80]. The stirred mixture of acids was cooled at 258 to 263 K ( $-15$  to  $-10^\circ\text{C}$ ) and urea was dosed at such a rate as to keep the reaction temperature below 273 K ( $0^\circ\text{C}$ ). The stirring was continued for 30 min at 273 to 268 K ( $0$  to  $-5^\circ\text{C}$ ). The precipitate of crude DNU was filtered, rinsed cold, and used as the starting material in further reactions. At room temperature, particularly in the presence of water and traces of acids, DNU underwent decomposition, which may lead to spontaneous ignition. Pure DNU has an ignition temperature of  $420 \pm 9$  K ( $147 \pm 9^\circ\text{C}$ ). The stability of DNU strongly depends on its purity. The crude, separated DNU still containing nitrating acids, kept at 298 K ( $25^\circ\text{C}$ ) for 20 min, may undergo self-ignition. Attempts at DNU purification by recrystallization from diethyl ether and careful drying in a vacuum were unsuccessful. Partial hydrolysis of substrate occurred during formation of DNU salts. Besides  $\text{CO}_2$ , nitramine was the main hydrolysis by-product and it decomposed into  $\text{N}_2\text{O}$  and  $\text{H}_2\text{O}$ .

The diammonium salt of dinitrourea was obtained in direct synthesis from crude DNU and aqueous ammonia (13%) at 293 K (20 °C). The product precipitated as a colorless solid. The ammonium salts originating from acidic impurities of DNU remained in the supernatant solution. The product was separated by filtration, washed a few times with ice-cold water, and dried in a vacuum desiccator over silica gel.

Under similar conditions (similar to those described in [80]), namely 100%  $\text{HNO}_3$ /20% oleum (V/V) ratio = 0.6/1, temperature of the first stage at 258 K (−15 °C) and temperature of the second stage at 278 K (+5 °C), reaction time 50 min, the yield of dinitrourea was 83.2% of theory [81]. The thermodynamic properties at different temperatures were obtained from vibrational analysis. Results showed that dinitrourea has two stable conformations with an energy difference of 12.621 kJ/mol. The calculated vibrational frequencies and intensities of DNU IR spectra were in good agreement with the experimental values.

Depending on the reaction conditions and the type of nitrating agent used, not only the symmetrical dinitrourea (**1**), but also the unsymmetrical dinitrourea with two geminal nitro groups (**2**) may be formed

The 1,1-dinitrourea (**2**) is not stable, but it is an important intermediate in the synthesis of dinitramides (see *Encyclopedia of Oxidizers*, chapter “Dinitramide Oxidizers”).

A study of the hydrolysis of *N,N'*-dinitrourea resulted in the development of a convenient method for synthesizing nitramide on the basis of urea and the discovery of new reactions of nitramide [82, 83]. The availability of *N,N'*-dinitrourea salts made it possible to synthesize new nitramine compounds [84]. Symmetric *N,N'*-dinitrourea is a fairly strong dibasic acid which is capable of undergoing stepwise ionization with formation of acid and neutral salts:

The existence of acid salts of the **I** type was proved by physical methods. Neutral salts **II** were formed on prolonged heating of aqueous solutions of acid salts. The reaction of *N,N'*-dinitrourea with hydrazine yielded 4-nitrosemicarbazide, and the reaction with hydroxylamine lead to *N*-hydroxy-*N'*-nitrourea.

Reactions of *N,N'*-dinitrourea with formaldehyde, depending on the conditions of the reaction, may lead to formation of various hydroxymethyl derivatives of *N*-nitroamines and products of their further condensations [85]. The condensation of *N,N'*-dinitrourea with formaldehyde at a molar ratio of 1:1 in aqueous solution in the presence of sulfuric acid at 293–353 K (20–80 °C) gave an oily substance whose IR spectrum suggested the presence of CH<sub>2</sub>, OH, NH, and NNO<sub>2</sub> groups. Its UV spectrum contained an absorption near 226–228 nm, which was characteristic of the expected product *N,N'*-dinitromethylenediamine.

Treatment of this product with KOH yielded a dipotassium salt with yields up to 89%, depending on the temperature and reaction time.

### 8.2.2 Physical Properties of Dinitrourea

Dinitrourea melts at 474–477 K (101–104 °C) in a capillary and at 480–483 K (107–110 °C) on a hot-stage microscope. The density is 1.98 g/cm<sup>3</sup> at room temperature. Dinitrourea is soluble in water, acetonitrile, alcohols, ether, ethyl acetate, cyclohexanone, THF, DMSO or nitric acid. However, aqueous solutions of DNU decompose quickly.

### 8.2.3 Decomposition of Dinitrourea

The thermal decomposition of the diammonium salt of DNU proceeded in stages: the first mol of NH<sub>3</sub> was removed at up to 383 K (110 °C; weight loss 10%, 9.24% calcd.) [80]. The second much faster stage of decomposition was connected with releasing the second mol of ammonia, until at 403 K (130 °C), the total weight loss was ~18%. At the end of the second stage the decomposition of DNU itself began and ended at 413 K (140 °C), with a spontaneous complete decomposition of the sample. A much more thermostable compound is the potassium salt of DNU. The beginning of the decomposition was observed at 408 K (135 °C), but ignition did not take place below around 463 K (190 °C). A hexamethylenetetramine salt of dinitrourea was obtained in a reaction of crude DNU with a 15 mass-% aqueous solution of (CH<sub>2</sub>)<sub>6</sub>N<sub>4</sub> at 293 K (20 °C). It was not as stable as the potassium salt.

The lack of stability of DNU reported by Syczewski, Cieslowska-Glinska, and Boniuk in [80] was later disputed. Later investigators found that when DNU was very pure, it could indeed be stored at room temperature [86]. In the DSC at a heating rate of 10 °C/min, the exotherm started at 373 K (100 °C) and was very steep at 393 K (120 °C). The ignition temperature in a Wood's metal bath was at 364–366 K (91–93 °C). The activation energy by DSC was 104 kJ/mol and from the ignition delay it came out to be 78 kJ/mol. The measured density was 1.98 g/cm<sup>3</sup> at 298 K (25 °C). The drop-weight impact sensitivity was 5 J (for comparison: RDX 7 J) and the friction sensitivity was 76 N (for comparison: RDX 120 N). See also [87].

The thermal decomposition mechanism of DNU was studied by temperature-programmed *in situ* pyrolytic FTIR spectroscopy [88]. The results showed that the nitro group of the DNU molecule is initially broken, followed by a rearrangement. All the decomposition reactions had gone to completion before the sample reached 373 K (100 °C), resulting in the formation of N<sub>2</sub>O, NO<sub>2</sub>, CON, HNCO, and NO<sub>2</sub>NH<sub>2</sub>. Theoretical calculations confirmed that the *syn*, *anti* conformations play a key role in the decomposition process and that the N—N bonds were broken firstly with the increase of temperature. The plotted potential energy curve via the corresponding bond length showed that cleavage of the N—N bond in the condensed phase of DNU was a highly reversible process and a typical radical recombination reaction with zero barriers in the initial step. The final products of N<sub>2</sub>O, NO<sub>2</sub>, HNCO, and NO<sub>2</sub>NH<sub>2</sub> were formed by  $\alpha$ -cleavage or hydrogen atom rearrangement of the radicals that were formed in the initial step.

### 8.2.4 Salts of Dinitrourea

Dinitrourea is a fairly strong acid. The  $pK_a$  value of the first stage of ionization is  $pK_{a1} = -0.13$ . The  $pK_a$  value of the second stage of ionization is  $pK_{a2} = 4.87$ :

The behavior of dinitrourea and its potassium and dipotassium salts in different solvents have been studied by IR and UV spectroscopy [89]. In different media, dinitrourea can exist in several tautomeric forms. An XRD study of the potassium and dipotassium salts of dinitrourea revealed a tendency toward equalization of the bond lengths of the C—N<sup>−</sup>—NO<sub>2</sub> fragments compared to those of C—NH—NO<sub>2</sub>, which agreed with the results of quantum chemical calculations.

The crystal structure of DNU was determined by single-crystal XRD and was found to be orthorhombic; space group: *Fdd2*,  $a = 12.0015(9) \text{ \AA}$ ,  $b = 17.6425(13) \text{ \AA}$ ,  $c = 4.5555(4) \text{ \AA}$ ,  $V = 964.57 \text{ \AA}^3$ ,  $Z = 8$ ,  $T = 90 \text{ K}$ ,  $\rho_{\text{XRD}} = 2.067 \text{ g/cm}^3$  [90]. The heat of formation ( $\Delta H_f^{298}$ ) of DNU vapor in the gas phase was calculated to be 24.88 kJ/mol using a method based on isodesmic reactions. Eleven mono-organic salts of DNU were prepared in acetonitrile and characterized via NMR spectra, elemental analyses, and DSC. Derivatives of 1,2,4-triazolium salts of DNU exhibited densities ranging from 1.75 to 1.86 g/cm<sup>3</sup> and detonation properties comparable to those of RDX and 1,3,5,7-tetranitro-1,3,5,7-tetraazacyclooctane (HMX).

Ten DNU dianionic salts formed by the metathesis of tetrazolium and guanidinium sulfates with *in situ*-generated barium DNU in aqueous solution were examined for impact sensitivity, NMR, elemental analysis, IR, DSC, and TGA [91]. Bis(guanylguanidinium) DNU dianionic salt crystallized in the triclinic space group *P*-1. The detonation pressures calculated for these salts range from 19.6 to 29.1 GPa,

and the detonation velocities ranged from 7521 to 8908 m/s, which make them competitive energetic materials. The DNU dianion compares very favorably with dinitramide as a novel oxidative species.

Six energetic DNU ionic salts were prepared by the reaction of ethylenediamine (EDA) and derivatives of triazole and imidazole with *N,N'*-dinitrourea [92]. Among them, EDA gave diacidic salt and other derivatives gave monoacidic salts. The effects of solvent, reaction temperature, and time on yield of salt from 4-aminotriazole and DNU were analyzed. The yield could be up to 85% in acetonitrile and 71% in ethanol at 10 °C for a 2-h reaction time. Generally, polar solvents with high dielectric constants were beneficial to the salt-forming reaction. The structures of all salts prepared were confirmed by IR, <sup>1</sup>H NMR, <sup>13</sup>C NMR, and elemental analysis. The thermal stability of most salts surpassed that of DNU. For instance, EDA-DNU salt started to decompose at 398 K (125 °C; approximately 55 °C higher than DNU).

Additional information on salts formed from DNU is referenced in [79]. The IR spectrum of the crystalline monopotassium salt indicated that one of the two nitramine groups, which is not involved in salt formation, has the true structure of a nitramine (doublet: 1620, 1600 cm<sup>-1</sup>), and the proton participates in either inter- or intra-molecular hydrogen bonding with oxygen atoms of the nitro and carbonyl groups, as the proton's vibrational frequency decreased to 3180, 3220 cm<sup>-1</sup>. The IR spectrum of the dipotassium salt of DNU differed from both the IR spectrum of DNU and that of the DNU monopotassium salt. The difference lies, first, in lacking any band within the region of 3600–3000 cm<sup>-1</sup> (N–H group and hydroxonium ion) and within the region of 1530–1620 cm<sup>-1</sup> (asymmetric vibrational frequencies of the nitro group), and second, in the observed vibrational frequencies for both nitro groups in the *aci*-form N=NO(OK)(1390, 1380, and 1210 cm<sup>-1</sup>).

### 8.3 Ring-Shaped Nitrourea and Dinitrourea Derivatives

Instead of leaving the amide group dangling at the end of the linear molecule, there are several ways to close the ring using the terminal –NH<sub>2</sub> group and performing an –NH– ring closure. Compounds that contain the –NH–CO–NH– sequence in small ring structures are sometimes called **urils**, to indicate their relationship to **urea** H–NH–CO–NH–H. Energetic compounds are then obtained by replacing the hydrogen on the NH group and converting the amido groups to nitramino –N(NO<sub>2</sub>) groups. These compounds could be discussed in later chapters in this book under nitramines (*Encyclopedia of Liquid Fuels*, chapter “Nitramines”) or heterocyclic amines (chapter “Heterocyclic Amines”), but because of their close relationship to **urea**, they are already discussed here.

The earliest and best-known examples of bicyclic mono- and dinitroureas were 1,3,4,6-tetranitroglycouril (TNGU) and 1,4-dinitroglycouril (DNGU or DINGU) [93–97]. TNGU can be processed in prilled particle form [98]. This spherical morphology was

significantly less sensitive to impact, friction, and electrostatic discharge than crystalline TNGU made according to literature methods. DNGU was first described in 1888, but received little attention until 90 years later.

TNGU

DNGU

Both TNGU and DNGU have high crystal densities (2.04 and 1.98 g/cm<sup>3</sup>, respectively). TNGU is unstable in the presence of water and hydrolyzes [99], while DNGU decomposes only slowly even in boiling water. DNGU has a significantly higher drop hammer value (i.e., less sensitive) than TNGU and is more stable. DNGU has been proposed as an RDX and TNT replacement. When compacted to a bulk density of 1.94 g/cm<sup>3</sup>, TNGU exhibited a detonation velocity of 9073 m/s. DNGU has no melting point before decomposition. DNGU has a sharp exothermic transition at 518–523 K (245–250 °C). The impact sensitivity was 80–100 cm in the Holston apparatus (for comparison: RDX: 17 cm) and the friction sensitivity was 360 N (for comparison: RDX: 164 N).

Similar uriles with only one carbonyl group and the other carbonyl group replaced by a methylene bridge also have good explosive properties. These compounds contain only one  $\text{—N(NO}_2\text{)—CH}_2\text{—N(NO}_2\text{)—}$  nitramide sequence instead of three as in RDX or four as in HMX.

K55

HK55

HK56

Pagoria et al. [100] also prepared K-56 in a shorter synthesis route from 1,4-diformyl-2,3-dihydropiperazine, which undergoes a condensation reaction with urea (in aq. HCl) to yield 2,5,7,9-tetrahydro-2,5,7,9-tetrazabicyclo(4.3.0)nonane-8-one dihydrochloride, followed by nitration with fuming nitric acid and acetic anhydride. Another nitrolysis agent is trifluoromethanesulfonic acid anhydride/20%  $\text{N}_2\text{O}_5$ /fuming nitric acid. K-56 has a density of  $1.969 \text{ g/cm}^3$ , while HK-56 has a density of  $1.84 \text{ g/cm}^3$  [100].

DNGU can be produced by a simple nitration of glycoluril, which is very inexpensive [101]. Glycoluril can be produced from very inexpensive materials (urea and glyoxal). Glycoluril is commercially available and the cost of DNGU was estimated to be between that of RDX and that of HMX. Yields are typically 90–95%, with purities 99%.

Continued nitration of DINGU leads to the tetranitramine also called SORGUYL (same as TNGU). SORGUYL has a very high density ( $2.01 \text{ g/cm}^3$ ) and a very high detonation velocity ( $9150 \text{ m/s}$ ).

Tetranitrodiglycoluril (TNDGU) can be synthesized from glycoluril dimer [102]. TNDGU is a primary explosive with a density of  $1.93 \text{ g/cm}^3$  and a detonation velocity of  $8305 \text{ m/s}$ . It will probably not be used as a rocket propellant.

## 9 Oxamide and Oxalyldihydrazide

The three compounds oxamide, oxalylmonohydrazide (oxalic acid monhydrazide), and oxalyldihydrazide (oxalic acid dihydrazide) are useful high-nitrogen compounds and are used as coolants for gas generants. Physical properties of these compounds are listed in Table 4. Additional information on oxamide is found in [103]. Procurement and purity requirements of oxamide are covered by specifications AS-1871 and MIL-O-60863.

**Table 4:** Properties of oxamide, oxalylmonohydrazide, and oxalyldihydrazide.

|                          | Oxamide                                                     | Oxalylmonohydrazide                                         | Oxalyldihydrazide                                           |

The protonation of oxalyldihydrazide with nitric acid gives oxalyldihydrazinium nitrate (OHN) and dinitrate (OHDN) [104]. The synthesis is very simple and can be carried out on large scales and with very good yields. OHN and OHDN were intensively characterized by low-temperature XRD, NMR, and vibrational spectroscopy. These salts could be used as ingredients in energetic formulations due to their low sensitivities and high nitrogen contents. Their thermal stability was investigated by DSC and the salts were very thermally stable.

## 10 Cyanamide

Cyanamide, also known as cyanamid, carbamonitrile, H<sub>2</sub>N—C≡N, CAS RN [420-04-2] is an important intermediate in the synthesis of high-nitrogen compounds like triaminoguanidine and its salts, and readily cyclizes to heterocyclic compounds with nitrogen(s) in the ring. It forms colorless, hygroscopic crystals. Cyanamide as an acid

forms ionic liquid salts that are under consideration as low-volatility hypergolic fuels with less toxicity than alkylhydrazines. The cyanamide anion is sometimes called a cyanamidate anion. Cyanamide in aqueous solution is stable at pH < 5, but will dimerize to dicyandiamide at pH 8–9.5.

Calcium cyanamide was once used as a fertilizer before nitrogen from the Haber–Bosch synthesis of ammonia became the main source of fertilizer nitrogen.

Cyanamide contains both a nucleophilic and an electrophilic group within the same molecule, and so cyanamide undergoes various reactions with itself. Cyanamide exists as two tautomers

the cyanamide form and the carbondiimide form. The  $\text{N}\equiv\text{CNH}_2$  form dominates, but in a few cases, the imide configuration forms the path for reactions.

Cyanamide dimerizes readily to give 2-cyanoguanidine (dicyandiamide, see section “Dicyandiamide (2-Cyanoguanidine)”) and trimerizes to a cyclic trimer which is called melamine. Unstabilized cyanamide may polymerize spontaneously while stored at room temperature. Therefore, most cyanamide is not stored as such, but converted to dicyandiamide or melamine for further use. A large American chemical company once carried the term “Cyanamid” in its name. The physical properties of cyanamide are summarized in Table 5.

**Table 5:** Properties of cyanamide.

| Property              | SI units                            | Other units                                 | References |
|-----------------------|-------------------------------------|---------------------------------------------|------------|
| Molecular mass        | 42.0400 g/mol                       | 23.787 mol/kg                               | [105]      |
| Melting point         | 315 K                               | 42 °C                                       | [106]      |
| Boiling point         | 356 K at 6.7 Pa<br>413 K at 2.5 kPa | 83 °C at 0.05 mm Hg<br>140 °C at 18.7 mm Hg | [106]      |
| Density               | 1.282 g/cm <sup>3</sup>             | —                                           | [106]      |
| Enthalpy of formation | +58.79 kJ/mol                       | +14.05 kcal/mol                             | [105]      |
| Heat of fusion        | 8.76 kJ/mol at 317 K                | 2.09 kcal/mol at 44 °C                      | [105]      |
| Heat of sublimation   | 75.2 kJ/mol at 290 K                | 17.97 kcal/mol at 17 °C                     | [105]      |

When stored under moist conditions, cyanamide degrades via hydrolysis to urea. Heating cyanamide in an autoclave can form graphitic carbon nitride (g  $\text{C}_3\text{N}_4$ ).

## Imides

Imides contain the  $>\text{C}=\text{NH}$  group where an amide would contain a  $>\text{C}=\text{O}$  group. Imides are of more interest as propellants than the  $>\text{C}=\text{O}$  compounds from which they are often derived because they have higher enthalpies of formation and a better fuel value. Nobody likes  $>\text{C}=\text{O}$  bonds in a fuel.

## 11 Guanidine

Guanidine,  $\text{H}_2\text{NC}=\text{NH NH}_2$ ,  $\text{C}_1\text{H}_5\text{N}_3$ , CAS RN [113-00-8], itself, the free base, is rarely used as an ingredient in rocket propellants because it is not as stable as the guanidinium salts derived from it.

Guanidinium salts have a useful high nitrogen content and a remarkable thermal stability. Actually, guanidine is amphoteric and can form salts with both acids and with very strong bases. Alkali metal guanidates have been prepared and characterized.

Guanidine melts and decomposes at 323 K ( $50^\circ\text{C} = 122^\circ\text{F}$ ). The heat of combustion is 1052 kJ/mol and the standard enthalpy of formation  $\Delta H_f^{298}$  is  $-56$  kJ/mol. The  $\text{p}K_a$  of guanidine in water is 13.6, meaning that guanidine is a very strong base. Guanidine free base is difficult to obtain in the pure state and that difficulty has delayed the characterization of its molecular structure [107–109]. The crystal structure consists of two Y-shaped symmetry-independent molecules in the unit cell that are interconnected by a hydrogen bonding network, which results in a layered structure. Pure guanidine crystallizes in the orthorhombic space group *Pbca* (No. 61) with the cell parameters of  $a = 8.5022(2) \text{ \AA}$ ,  $b = 9.0863(2) \text{ \AA}$ ,  $c = 15.6786(4) \text{ \AA}$  at 100 K,  $Z = 16$ , with two Y-shaped molecules in the asymmetric unit [110].

The theoretical gas-phase enthalpies of formation of guanidine and its ten amino and nitro derivatives were calculated using an isodesmic reaction method [111]. The enthalpies of sublimation were estimated within the framework of the Politzer approach that combined the empirical equation for enthalpy of sublimation with the quantum mechanical calculations of the electronic properties of the molecular surfaces. The enthalpies of sublimation of mono-, di-, and triaminoguanidine were calculated using experimental data for their salts. On the basis of the calculated enthalpies of formation in the gaseous state and enthalpies of sublimation values, the solid-phase enthalpies of formation were estimated for all guanidine derivatives. Results from a predictive model agreed with available experimental data for guanidine, nitroguanidine, and some of their derivatives.

Guanidine free base would never be used as a fuel in rocket propellants, but it is a good intermediate in the synthesis of heterocyclic compounds and special guanidinium salts.

Fluorination of urea or guanidine was intended as a step in the synthesis of energetic difluoroamino compounds. However, side reactions prevented formation of the desired products. The reaction of guanidine in solution with  $\text{ClO}_3\text{F}$  did not give the desired *N*-fluoro- or *N,N'*-difluoroguanidine, but instead yielded guanidinium salts  $\text{C}(\text{NH}_2)_3^+\text{X}^-$  ( $\text{X} = \text{F}, \text{ClO}_4$ ) [112, 113].

### 11.1 Guanidinium Salts

Guanidine is a strong base and forms salts with many acids, even weak proton donor acids. Many of the salts are thermally stable and contain a high nitrogen content, making them promising ingredients for propellants and gas generators. Table 6 is a summary of CAS registry numbers, gross formulae, molecular mass, oxygen balance, and nitrogen content of guanidinium nitrate and a few derived compounds. See also [114].

Table 7 is a summary of the melting points of guanidinium salts.

**Table 6:** Molecular mass, nitrogen content, and oxygen balance of guanidinium nitrates.

| Name                        | CAS RN     | Gross formula                              | Molecular mass | Oxygen balance, % | Nitrogen content, mass% |
|-----------------------------|------------|--------------------------------------------|----------------|-------------------|-------------------------|
| Guanidinium nitrate         | 506-93-4   | $\text{C}_1\text{H}_6\text{N}_4\text{O}_3$ | 122.0833       | -26.2             | 45.89                   |

**Table 7:** Summary of melting points of guanidinium salts.

| Compound name           | Gross formula                                 | Melting point |          | References |
|-------------------------|-----------------------------------------------|---------------|----------|------------|
|                         |                                               | K             | °C       |            |
| Guanidinium perchlorate | $\text{CH}_6\text{N}_3\text{O}_4\text{Cl}$    | 528           | 255      | [115]      |
| Guanidinium nitrate     | $\text{CH}_6\text{N}_4\text{O}_3$             | 488           | 215      | [18]       |
| Guanidinium carbonate   | $\text{C}_3\text{H}_{12}\text{N}_6\text{O}_3$ | 471           | 198      | [106]      |
| Guanidinium picrate     | $\text{C}_7\text{H}_8\text{N}_6\text{O}_7$    | 606           | 333 dec. | [18]       |
| Guanidinium dinitramide | $\text{C}_1\text{H}_6\text{N}_6\text{O}_4$    | 421           | 148      | [116]      |

## 11.2 Guanidinium Nitrate

Guanidinium nitrate,  $[\text{C}^+(\text{NH}_2)_3]\text{NO}_3^-$ ,  $\text{CH}_6\text{N}_4\text{O}_3$ , guanidine nitrate, GuN, GN, CAS RN [506-93-4], is a thermally very stable high-nitrogen compound. It contains a good amount of nitrogen (45.89% N), is used in gas generants for airbag inflators, and was used as the main ingredient in high-temperature explosives. It is the starting material for production of nitroguanidine.

### 11.2.1 Production of Guanidinium Nitrate

Guanidinium nitrate can be prepared by reacting cyanamide or dicyandiamide with nitrate in liquid ammonia [117]. Liquid ammonia is a solvent for cyanamide, dicyandiamide, and ammonium nitrate. Guanidinium nitrate can be prepared by fusing dicyandiamide with ammonium nitrate, which results in ammeline and ammelide as contaminant by-products. The mixtures of AN with any organic compounds like dicyandiamide are potentially explosive, in particular in the presence of organic contaminants. Another method used the reaction of urea and ammonium nitrate with silica gel as a catalyst, and the kinetics of the reaction were followed by measuring the formation of  $\text{NH}_3$  [118]. The optimum temperature for the maximum yield of guanidinium nitrate from urea and AN using silica gel as catalyst and with a given ratio of urea and AN had to be determined. See also [119, 120]. The effect of the mixture ratio of raw materials, reaction time, temperature, activity of the catalyst, and other parameters on the synthesis of GuN from urea and ammonium nitrate in the presence of catalyst and conversion of urea were investigated [121, 122]. The most favorable process conditions have advantages of economic raw materials and high yield.

### 11.2.2 Physical Properties of Guanidinium Nitrate

Table 8 gives a summary of the physical properties of GuN.

**Table 8:** Physical properties of guanidinium nitrate.

| Property                | SI units                    | Other units                    | References |       |
|-------------------------|-----------------------------|--------------------------------|------------|-------|
| Molecular mass          | 122.0833 g/mol              | 8.1911 mol/kg                  | —          | [105] |
| Melting point           | 488 K                       | 215 °C                         | 419 °F     | [18]  |
|                         | 487.17 K                    | 214.02 °C                      | 417 °F     | [123] |
|                         | 485.43                      | 212.28 °C                      | 414 °F     | [36]  |
| Density                 | 1.436 g/cm <sup>3</sup>     | —                              | —          | [124] |
|                         | 1.4365 g/cm <sup>3</sup>    | —                              | —          |       |
| Vapor pressure at 298 K | 2.66 × 10 <sup>−18</sup> Pa | 1.99 × 10 <sup>−20</sup> mm Hg | [16]       |       |

### 11.2.2.1 Vapor Pressure of Guanidinium Nitrate

The vapor pressure of GuN was measured at 478–498 K (205–225 °C) using an isothermal thermo-gravimetric weight-loss method and compared to that of urea nitrate and AN [16]. The Clapeyron equation for GuN vapor pressure is

$$\ln P = 72.189 - 33589/T$$

where  $P$  is the pressure in Pa and  $T$  is the temperature in kelvin. For a temperature of 298 K, this equation gives a vapor pressure of  $2.66 \times 10^{-18}$  Pa =  $1.99 \times 10^{-20}$  mm Hg. From the slope of this equation, the enthalpy of sublimation was calculated as 279 kJ/mol.

### 11.2.2.2 IR Spectra of Guanidinium Nitrate

Infrared spectra of GuN are shown in Figures 7 and 8.

**Figure 7:** Infrared spectrum of guanidinium nitrate. (Reproduced and modified from [21].)

**Figure 8:** Infrared spectrum of guanidinium nitrate. (Reproduced and modified from [125], with permission from Levering Estate.)

The IR spectra of GuN, aminoguanidinium nitrate, diaminoguanidinium nitrate, triaminoguanidinium nitrate, and several other compounds of interest are shown in Figure 8, 18, 21, and 24 [125–127]. The spectra were taken as a suspension of the compound to be studied in white mineral oil, and mineral oil absorption is always superimposed on the spectrum of the other compound. The main oil bands are shown as dotted lines, while the bands considered to be due to the compound under study are marked with a small vertical line. For the 20 guanidine derivatives presented in the paper, a strong absorption band was found in the region of 5.95 to 6.02  $\mu\text{m}$  in all but four cases; in these cases, a band was observed a few hundredths of a micron on either side of this region. As this band is in the region of the spectrum characteristic of double bonds, it has been attributed to the C=NH group present in all guanidine derivatives.

### 11.2.2.3 Thermodynamic Properties of Guanidinium Nitrate

Table 9 gives a summary of the thermodynamic properties of GuN.

**Table 9:** Thermodynamic properties of guanidinium nitrate.

| Property                  | SI units         |               | Other units              |              | References |
|---------------------------|------------------|---------------|--------------------------|--------------|------------|
| Molecular mass            | 122.0833 g/mol   | 8.1911 mol/kg |                          |              | [105]      |
| Enthalpy of formation     | –386.9           | –3169.2 kJ/kg | –92.47                   | –757.4 cal/g | [128,      |
|                           | $\pm 0.7$ kJ/mol |               | $\pm 0.17$ kcal/mol      |              | 129]       |
|                           | –387 kJ/mol      | –3170.1 kJ/kg | –92.5 kcal/mol           | –757.7 cal/g | [18]       |
|                           | –389             | 3186 kJ/kg    | $-93 \pm 0.93$ kcal/mol  | –761.7 cal/g | [130]      |
|                           | $\pm 3.9$ kJ/mol |               |                          |              |            |
| Heat of fusion            | –387.2 kJ/mol    | 3171 kJ/kg    | –92.54 kcal/mol          | –758 cal/g   | [124]      |

### Enthalpy of Formation of Guanidinium Nitrate

Because of interference due to the formation of nitric acid during combustion of GuN in a combustion bomb in a calorimeter, the heat of reaction of guanidinium perchlorate with nitric acid and the heat of reaction of GuN with perchloric acid in solution was measured and used to calculate the enthalpy of formation of GuN [130]. The heats of solution of the various reactants were determined in separate experiments for a wide range of dilutions. The experiments gave a value of  $-389 \pm 3.9$  kJ/mol ( $-93 \pm 0.93$  kcal/mol) for the standard enthalpy of formation of GuN. The same method was also used to obtain the enthalpy of formation of guanidinium perchlorate.

Enthalpies of formation and solution of guanidinium, aminoguanidinium, and triaminoguanidinium nitrate were determined by combustion and solution calorimetry methods [131]. Enthalpies of formation of the respective cations by themselves in infinitely diluted aqueous solution were then calculated using the known enthalpy of formation of the nitrate ion ( $-206.8$  kJ/mol =  $-49.44$  kcal/mol). The upper heats of combustion in a constant-volume calorimetric bomb, the enthalpies of formation, and the enthalpies of solution of the three nitrate salts are summarized in Table 10.

**Table 10:** Heats of combustion, enthalpies of formation, and enthalpies of solution of guanidinium and mono- and triaminoguanidinium nitrates.

#### 11.2.2.4 Solubility of Guanidinium Nitrate

Guanidinium nitrate is not very soluble in water and can be easily purified by recrystallizing from water. Based on very old data, the solubility of GuN in water is 160 g/kg  $\text{H}_2\text{O}$  at 293 K (20 °C), 470 g/kg  $\text{H}_2\text{O}$  at 328 K (55 °C), and 2000 g/kg  $\text{H}_2\text{O}$  at 373 K (100 °C). In boiling ethanol, one can dissolve 130 g GuN in 1 kg  $\text{C}_2\text{H}_5\text{OH}$  at 351 K (78 °C).

Using a gravimetric method, solubilities of GuN in water, methanol, ethanol, *n*-propanol, and acetone at temperatures ranging from 278 to 333 K at atmospheric pressure were experimentally measured [123]. Melting temperature,  $T_m$ , and fusion enthalpy,  $\Delta H_f$ , of guanidinium nitrate were determined using DSC. Dissolution of GuN in all examined solvents was found to be endothermic and entropically favorable. The measured solubility data were combined with calculated ideal solubility data to

calculate activity coefficients at infinite dilution. Solubility data for GuN in water, methanol, and ethanol are summarized in Table 11. The heat of dissolution of GuN in water is 24.41 kJ/mol, in methanol 23.80 kJ/mol, and in ethanol 23.23 kJ/mol.

**Table 11:** Solubility of guanidinium nitrate in three different solvents.

### 11.2.3 Thermal Stability of Guanidinium Nitrate

The TGA showed that GuN started losing weight at 503 K (230 °C) and the decomposition was fast between 548 and 598 K (275–325 °C) [132]. Compared to all other organic nitrate salts, this is a very high decomposition temperature. Guanidinium nitrate is thermally very stable. The weight loss was slow in the temperature range 598–773 K (325–500 °C). No residue was left behind at 773 K (500 °C), which suggested that the entire mass had been converted into gaseous products. The activation energy calculated by analyzing was 192.5 kJ/mol (46 kcal/mol). The DTA showed an endotherm at 483 K (210 °C) and an exotherm at 578 K (305 °C). As the compound melts at 483 K (210 °C) and since there is no weight change around this temperature, the endothermic peak is due to the melting of GuN. Analyzing the decomposition products in a mass spectrometer at 503 K (230 °C), there was no indication of a molecular peak corresponding to GuN, which suggests that the decomposition process occurs through a proton transfer mechanism as observed in similar onium-type salts. It is interesting to note that the fragmentation product, cyanamide ( $m/e = 42$ ), undergoes dimerization to cyanoguanidine ( $m/e = 84$ ) and trimerization to melamine ( $m/e = 126$ ).

Infrared spectroscopy measurements of the kinetics and decomposition pathways of aqueous GuN solutions at 513–573 K (240–300 °C) and 275 bar showed that the decomposition of GuN was catalyzed by the formation of  $\text{NH}_3$  [133]. The reaction

scheme involved deprotonation of the guanidinium ion by  $\text{NH}_3$  to produce neutral guanidine, which hydrolyzed to form urea as the rate-determining step. The subsequent hydrothermolysis chemistry followed that of urea. Thus, although the overall decomposition rate of GuN was slower than that of urea, the Arrhenius parameters for the step for formation of  $\text{CO}_2$  from GuN and urea were similar ( $E_a \approx 66 \text{ kJ/mol}$ ,  $\ln A \approx 19 \text{ s}^{-1}$ ).

The first endothermic peak seen at 487 K (214 °C) in the DTA thermogram of GuN at a heating rate of  $2^\circ/\text{min}$  is the phase change from solid to liquid (Figure 9) [134]. After this phase change, a very slow decomposition reaction occurred. The major decomposition of GuN began only at 505 K (232 °C) and was complete at 576 K (303 °C; 75% weight loss). The remaining 25% weight residue decomposed endothermically at higher temperature.

**Figure 9:** DTA-TGA thermogram of guanidinium nitrate. (Republished and modified from [134], with permission of ©2009 Elsevier Science Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

The DSC thermogram recorded at a heating rate of  $10^\circ\text{C}/\text{min}$  in nitrogen atmosphere showed a similar behavior (Figure 10). The melting endotherm appeared between 475 and 493 K (202 and 220 °C), with a peak temperature at 488 K (215 °C). The exotherm between 563 and 598 K (290 and 325 °C), with a peak temperature at 576 K (303 °C), indicated that the slow decomposition of GuN took place at a higher temperature as compared to that of TAGZ (see Section 14.5 “Triaminoguanidinium Azide” below).

The decomposition of GuN was examined by isothermal heating followed by quantification of both remaining nitrate and remaining base [36]. Activation energies determined for GuN were 199 and 191 kJ/mol with pre-exponential factors  $1.94 \times$

**Figure 10:** DSC thermogram of guanidinium nitrate. (Republished and modified from [134], with permission of ©2009 Elsevier Science Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

$10^{15} \text{ s}^{-1}$  and  $3.20 \times 10^{14} \text{ s}^{-1}$  for nitrate and guanidine, respectively. Decomposition products, both gaseous and condensed, were analyzed and decomposition routes were suggested. Experimental results indicated that  $\text{NO}_2^+$  might be generated during the decomposition. This mechanism appeared to differ from that of the analogous nitro derivatives. For guanidinium nitrate, several possible decomposition routes can be envisioned: A decomposition pathway for GuN proceeding via dissociation to nitric acid would be analogous to that proposed for AN and UN. This is essentially the reversal of GuN synthesis. Dissociation

and subsequent decomposition of nitric acid and reaction with ammonia would explain the observed acceleration in the presence of acids. Nitroguanidine can be formed by dehydration of GuN and its decomposition also produces ammeline and melamine. Subsequent reaction would give cyanamide and nitramine, which rapidly undergo further decomposition

Cyanamide can combine to give a multitude of cyclic products. Unlike AN and UN, GuN decomposition is accelerated by basic species as well as by acids. Reaction pathways involving water loss would explain such sensitivity. Nitroguanidine may also be formed by the dehydration of GuN. Its decomposition also produces ammeline and melamine. Subsequent reactions would give cyanamide and nitramine, which rapidly undergo further decomposition. A DSC thermogram of GuN decomposition in sealed glass capillary tubes under nitrogen at a heating rate of 20°/min is shown in Figure 11.

**Figure 11:** DSC thermogram of guanidinium nitrate decomposition. (Republished and modified from [36], with permission of ©2009 Taylor & Francis, [www.tandfonline.com](http://www.tandfonline.com).)

The thermal decomposition of GuN was analyzed using a combined experimental and computational approach [135]. Concurrent TGA-FTIR-MS experiments were carried out at three different heating rates under closed- and open-crucible conditions. A two-stage decomposition process was observed, and the major gases evolved were found to be  $\text{NH}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}_2$ , and  $\text{CO}_2$ . Results of quantum mechanics-based *ab initio* computations indicated that decomposition of GuN is not initiated in the condensed phase, because the guanidinium cation and the nitrate anion are highly stable. The most likely mechanism involves isomerization of GuN followed by a proton transfer in the gas phase to yield nitric acid and guanidine. These products then further react to form nitroguanidine (NQ) and  $\text{H}_2\text{O}$ . NQ dissociates via several competing pathways to yield  $\text{NH}_3$ ,  $\text{N}_2\text{O}$ ,  $\text{H}_2\text{O}$ , and  $\text{CO}_2$ .  $\text{HNO}_3$  formation and decomposition can help to explain  $\text{NO}_2$  formation. The residue left towards the end of TGA can be attributed to dimerization and trimerization reactions of cyanamide. See also [136].

The thermal decomposition of GuN and basic cupric nitrate (GuN/BCN) mixtures in five different mass ratios intended to be used as gas-generating agents for airbag inflation was investigated by TGA-DSC-MS-FTIR and automatic calorimeter [137]. It was shown that the onset reaction temperatures of GuN/BCN mixtures were lower than that of GuN alone. The thermal decomposition of GuN/BCN mixtures could be subdivided into three stages, including the dissociation and escape of crystal water, solid (GuN)-solid (BCN) phase reaction, and liquid (GuN)-solid (BCN) phase reaction. When the mass ratio of GuN/BCN was 62.24/37.73, the largest value of the reaction heat was measured at 3152.7 J/g, with  $N_2$  and  $H_2O$  as the major gases produced during thermal decomposition.

A combined TGA/DSC/FTIR investigation indicated that the GuN/BCN mixture underwent endothermic decomposition at 443 K (170 °C) and exothermic decomposition at 481 K (208 °C), which was accompanied by 66% mass loss [138]. The decomposition gases,  $CO_2$ ,  $N_2O$ , and  $H_2O$ , were detected via FTIR spectrum. Because  $N_2O$  was not detected in the hot combustion gas, it was suggested that the detected  $N_2O$  was generated at a low temperature and decomposed in high-temperature combustion. See also [139].

The decomposition mechanism of GuN was investigated by quantum chemistry calculations and optimized structures of reactants, products, and transition states were obtained and the total electron energies and free energies of these structures were calculated [140]. In the initial decomposition pathway of GuN, two mechanisms occur in parallel:  $CN_3H_5$  decomposition and the interaction between  $CN_3H_5$  and  $HNO_3$ . The former mechanism has three pathways and each of these schemes provided the same global reaction:

Other pathways for neutral monomolecular decomposition are **(1)** neutral-neutral bimolecular decomposition ( $CN_3H_5 + CN_3H_5$ ) and **(2)** cation-neutral bimolecular reaction ( $CN_3H_6^+ + CN_3H_5$ ). The latter reaction has four pathways and each of these schemes provided the same global reaction:

Based on the calculated energy barrier results,  $HNO_3$ -catalyzed monomolecular decomposition for  $CN_3H_5$  decomposition and  $N_2O_5/CN_3H_5$  schemes for the interaction between  $CN_3H_5$  and  $HNO_3$  are the most plausible mechanisms.

The thermal decomposition of GuN was studied at different linear heating rates of 5, 10, 15, and 20 K/min. [141]. The average extrapolated TGA mass loss onset temperature was 580 K. The average activation energies were 140.43 or 137.82 kJ/mol, respectively, depending on the method used for data reduction. The spontaneous ignition temperatures were 530 and 548 K, respectively.

### 11.2.3.1 Thermal Stability of Guanidinium Nitrate Mixtures

Mixtures of AN and GuN have better thermal stability than AN alone [142]. The kinetics of heat release during the thermal decomposition of GuN and AN and their mixtures in the liquid phase in a calorimeter were studied by DSC. The temperature dependence of the kinetic constants in these equations gives the activation energy. The oxidation rate constants of guanidinium and ammonium cations with molecular nitric acid in aqueous nitric acid solutions were calculated by solution of the reverse problem for salt melts. The temperatures and  $\Delta H$  values of melting of the initial salts and their eutectic mixture were determined. The DSC of AN/GuN eutectics still shows the somewhat weakened phase transitions of AN at 327 and 362 K (54 and 89 °C) [143].

A eutectic mixture of 85 parts aminoguanidinium nitrate and 15 parts GuN melts at 399 K (126 °C). Eutectic mixtures of aminoguanidinium nitrate with AN, also stabilized with small amounts of potassium nitrate and bonded with polyvinyl alcohol, were patented as airbag inflator gas generants [144].

Sealed-cell DSC, TGA-DTA-IR, and TGA-DTA-MS were used to study the thermal decomposition of 1,2,4-triazole-3-one (TO) and GuN mixtures which can be used as gas generants in airbag inflators [145]. The endothermic peak and onset of exotherm temperatures of TO/GuN mixtures were lower than those of individual TO and GuN pure compounds.

### 11.2.4 Toxicity of Guanidinium Nitrate

#### 11.2.4.1 Oral Toxicity of Guanidinium Nitrate

The acute oral toxicity of GuN was determined in male and female albino Sprague–Dawley rats administered a single dose by oral gavage [146]. The median lethal doses (MLD) were  $989.6 \pm 68.7$  mg/kg in male rats and  $729.8 \pm 34.3$  mg/kg in female rats. Clinical signs were behavioral changes (e.g., inactive, irritable, disoriented, hyperactive, ataxic) and were observed in 63 of 99 animals dosed with GuN. These observations suggested that guanidine nitrate is a slightly toxic compound with a primary effect on the central nervous/neuromuscular system.

In similar tests with male and female ICR mice, the median lethal dose was 1105 mg/kg for male mice and 1028 mg/kg for female mice [147]. Clinical signs included behavioral changes, hunched posture, and changes in reflex activity. Behavioral changes observed were irritability, inactivity, disorientation, hyperactivity, jumping, tremors, twitching, head tilt, catalepsy, and ataxia. The lethality and clinical signs were observed primarily during the first 24 h after dosing. These results place GuN in the slightly toxic category.

#### 11.2.4.2 Dermal Toxicity of Guanidinium Nitrate

The 24-h acute dermal toxicity of GuN was determined in rabbits [148]. No compound-related deaths or clinical signs other than dermal irritation were observed at a limit dose of 2 g/kg during this study. In a similar test, guinea pigs received three weekly

induction doses of 10% GuN solutions and, after a 2-week delay, a challenge dose at the same concentration [149, 150]. No evidence of GuN-induced skin sensitization was obtained in this study.

The eye irritation potential of GuN was determined in rabbits by a modified Draize method [151]. GuN caused mild-to-moderate irritation (erythema and chemosis of the conjunctiva, iritis, and corneal lesions).

The primary dermal irritation potential of GuN was determined in rabbits using a modified Draize method [152]. The compound was classified as a severe primary irritant with corrosive properties. Erythema, edema, and eschar formation was detected 24, 48, and 72 h after dosing. Irreversible skin damage was apparent at the time of sacrifice, 14 d after dosing.

### **11.2.5 Safety Properties of Guanidinium Nitrate**

#### **11.2.5.1 Shock Sensitivity of Guanidinium Nitrate**

The impact sensitivity of GuN in the BAM apparatus gave no reaction at impact energies up to 50 Nm. Likewise, in the BAM friction sensitivity tester, no reaction was observed at pistil loads up to 353 N.

#### **11.2.5.2 Detonability of Guanidinium Nitrate**

In a hazards analysis and safety design of facilities for manufacturing nitroguanidine by the urea/ammonium nitrate (U/AN) and the British aqueous fusion (BAF) processes, critical diameter, propagation, sensitivity, and thermal characteristics of a number of mixtures and compounds representative of selected streams in the processes were determined [153]. Critical diameter tests indicated that streams from the evaporator outlet, mixed reactor feed, and the liquid reactor outlet of the U/AN process will propagate detonation when initiated with a booster and that they are mass detonable. Propagation in 5.08-cm (2-in) pipes was not complete on any mixture containing  $\geq 25\%$  water. For comparison, the process streams in the wet guanidine nitrate mixtures used in the BAF process are not detonable. This is also true of cold melts (molten mixtures allowed to cool) in the event of plant shutdown. The sensitivity data on GuN alone showed that it is a relatively low-order explosive when compared to TNT, but that it is mass detonable. The detonation velocity of dense GuN would be 3700 m/s.

In the lead block test, the cavity is only slightly enlarged and the volume increase is  $240 \text{ cm}^3/10 \text{ g}$ . This is about 10% of the enlargement created by TNT.

#### **11.2.6 Applications of Guanidinium Nitrate**

Guanidinium nitrate samples from six different manufacturers representing at least two different synthetic processes were examined for gas generants in airbag inflators [154]. The two synthetic routes differed in starting materials, one being the fairly common dicyandiamide (DCDA) condensation with AN method while the other utilized urea and AN. Samples were first chemically and physically characterized and then

processed in a gas generant composition. Significant gas generant final property differences were noted as a function of GuN synthesis route. In general, material from the DCDA process, which represented the baseline, was found to be quite sensitive to source and impurity levels. Material prepared by the urea route appeared to possess higher purity than material manufactured by the DCDA process and tended to exhibit higher process viscosities and lower burning rates. The effect of the addition of various impurities to the GuN based on original sample analysis was also explored with respect to gas generant processing and ballistic properties, in an attempt to identify critical components requiring control.

Guanidinium nitrate was the main ingredient of a high-temperature-resistant explosive in a homogeneous molten mixture with sodium, potassium, and calcium nitrates that has been used for stimulating geothermal steam wells at very hot downhole temperatures [155].

### 11.3 Guanidinium Perchlorate

Guanidinium perchlorate, also known as guanidine perchlorate; guanidine, mono-perchlorate;  $\text{CH}_6\text{N}_3\text{O}_4\text{Cl}$ , GuP, GP, CAS RN [10308-84-6], is a thermally very stable high-nitrogen compound. It contains a good amount of nitrogen (26.35% N).

#### 11.3.1 Production of Guanidinium Perchlorate

Guanidinium perchlorate can be prepared by melting dicyandiamide with ammonium perchlorate (AP) or by metathetical reactions, like reacting guanidinium chloride with sodium perchlorate [156] or barium perchlorate in aqueous solutions. The metathetical reaction of guanidinium sulfate and barium perchlorate is quantitative and the product is easily separated from the precipitated barium sulfate [157]. A very straightforward preparation for the formation of guanidinium perchlorate is the reaction of guanidinium carbonate with perchloric acid in aqueous solution.

#### 11.3.2 Physical Properties of Guanidinium Perchlorate

Table 12 gives a summary of the physical properties of guanidinium perchlorate. Guanidinium perchlorate is a white, crystalline (cubic lattice), non-hygroscopic salt. Guanidinium perchlorate melts at 518–519 K (245–246 °C; [157]). Other reports state that it melts at 521 K (248 °C) and is thermally stable up to 650 K. A literature report of a GuP melting point of 451 K (178 °C) must have been in error and most likely was for an impure salt. The melting point of anhydrous GuP is close to that of  $\text{LiClO}_4$ , which is the only alkali metal perchlorate that melts without decomposition. At 453–455 K (180–182 °C), GuP undergoes a phase transition, but both phases possess a cubic crystal structure. The pycnometric density of GuP is  $1.743 \pm 0.04 \text{ g/cm}^3$  and the XRD density is  $1.772 \text{ g/cm}^3$ .

**Table 12:** Physical properties of guanidinium perchlorate.

| Property              | SI units                       | Other units     | References       |
|-----------------------|--------------------------------|-----------------|------------------|
| Molecular mass        | 159.5 g/mol                    | 6.269 mol/kg    | —                |
| Melting point         | 513 K                          | 240 °C          | 464 °F [18]      |
|                       | 518–519 K                      | 245–246 °C      | 473–475 °F [157] |
| Density               | 1.743 ± 0.04 g/cm <sup>3</sup> | —               | —                |
| Enthalpy of formation | −310 ± 2.9 kJ/mol              | −74.10          | −465 cal/g [130] |
|                       |                                | ± 0.55 kcal/mol |                  |

### 11.3.2.1 Crystal Structure of Guanidinium Perchlorate

A single-crystal X-ray analysis has shown that GuP crystallizes in the rhombohedral system with space group  $R3$  and hexagonal unit cell dimensions  $a = 7.606(2) \text{ \AA}$ ,  $c = 9.121(2) \text{ \AA}$ , and  $Z = 3$  [158]. Both the guanidinium cation and the perchlorate anion have a threefold symmetry axis and form hydrogen-bonded layers in which the N—H...O hydrogen bond is 3.06 Å in length. Nuclear magnetic resonance studies carried out on the polycrystalline compound revealed a considerable reduction in the second moment from 19.5 to 3.2 G<sup>2</sup> between 170 and 250 K, approaching zero above 454 K, as well as an asymmetrical T1 plot with a single minimum of 14 ms at 310 K. The nature of the solid-solid phase transition at 454 K appears to be related to the onset of cationic self-diffusion. A later refinement of the crystallographic data suggested the space group  $R3m$  rather than  $R3$  [159].

Guanidinium perchlorate undergoes a pressure-induced phase transition at high pressures up to ~11 GPa in a supramolecular structure held together by hydrogen bonding and electrostatic interactions [160]. *In situ* Raman spectroscopy and synchrotron XRD experiments have revealed a subtle phase transition accompanied by the symmetry transformation from  $R3m$  to  $C_2$ , evidenced by changes in both Raman and XRD patterns at 4.5 GPa. The phase transition is attributed to the competition between hydrogen bonds and close packing of the supramolecular structure at high pressure. Hydrogen bonds evolved into a distorted state through the phase transition, accompanied by a reduction in the separation of oppositely charged ions in adjacent sheet motifs.

Guanidinium perchlorate is a multi-axial ferroelectric material with a very high phase transition temperature of 454 K. This unusual dielectric property is one reason the GuP crystal structure has been thoroughly investigated, beyond the type of information needed to use it as a rocket propellant.

Guanidinium perchlorate single crystals were grown from aqueous solutions by low-temperature solution growth techniques and the cell parameters were measured using XRD [161]. The optical transmittance window and the lower cutoff wavelength were identified by UV-visible-near-IR (UV-VIS-NIR) spectral analysis. The dielectric constant was measured over a wide range of frequencies (100–5 MHz) and decreased

from 550 to 100 over this frequency range. The thermal stability of the crystals was studied using TGA (see Section 11.3.3.1).

### 11.3.2.2 Solubility of Guanidinium Perchlorate

GuP is somewhat soluble in water. The solubility is 31 mass-% GuP at 298 K (25 °C) and 11.5 mass-% at 273 K (0 °C). At 11.69 mass-%, GuP forms a eutectic with water which melts at 269.9 K (−3.2 °C) [157]. GuP crystallizes without water of hydration. GuP is very soluble in acetone (40.3 mass-% GuP at 298 K). In methanol at room temperature, only 30.2 mass-% GuP goes into solution.

The solubility of GuP in perchloric acid goes through a minimum and then rises to 36% in the anhydrous acid. A salt crystallizing from a saturated solution of GuP in perchloric acid was analyzed and turned out to be the guanidinium(2+) diperchlorate.

### 11.3.2.3 Melting Point of Guanidinium Perchlorate Mixtures

Guanidinium perchlorate forms a eutectic with AP at 9 mol-% AP, which melts at 490 K (217 °C) [162]. Guanidinium perchlorate/lithium perchlorate mixtures have a single eutectic at 49.5 mol-% LiClO<sub>4</sub> melting at 378 K (105 °C), and do not form double salts [163]. A break in the liquidus curve at 84.7 mol-% GuP at 454 K (181 °C) is due to the polymorphic transition of GuP. The referenced publication contains a graph illustrating the phase diagram for the entire range of compositions. These eutectic mixtures are useful as rocket propellants [164, 165].

The eutectic formed with GuP and tetrabutylammonium perchlorate consists of 35.5 mol-% [(NH<sub>2</sub>)<sub>3</sub>C]ClO<sub>4</sub> + 64.5 mol-% [(C<sub>4</sub>H<sub>9</sub>)<sub>4</sub>N]ClO<sub>4</sub>, and is an ionic liquid that melts at 255 K (82 °C) [166].

### 11.3.2.4 Vibrational Spectra of Guanidinium Perchlorate

The Raman and IR spectra of GuCl and GuP and their deuterated isotopomers were recorded at 300–3600 cm<sup>−1</sup> [167]. The solution IR spectra were independent of the anion present and are influenced by H-bonding in the solvents.

Near-IR spectra of guanidinium perchlorate (GuP) single crystals were recorded at 10 K in polarized light [168]. GuP contains planar guanidinium ions which lie on trigonal sites and are hydrogen bonded to the anions. The spectrum of guanidinium nitrate was also recorded, but its structure was not known at that time. The spectra showed clearly the effects of hydrogen bonding on the crystal structure.

The IR spectra of guanidinium compounds show very strong bands of stretching C–N vibrations ( $\nu_{\text{as}}\text{CN}$ ) in the range 1680–1570 cm<sup>−1</sup>. Bands in the IR spectrum at 1631 and 1556 cm<sup>−1</sup> with Raman counterparts observed at 1660 and 1639 cm<sup>−1</sup> were assigned to  $\nu_{\text{as}}\text{CN}$  type vibrations (Figure 12) [169, 170]. The phase transitions observed at 451 and 453 K were confirmed by IR spectra. The temperature changes in IR spectra suggested that the mechanism of phase transition is the result of forces derived by weak

**Figure 12:** Infrared and Raman spectrum of guanidinium perchlorate. (Reprinted and modified from [170], with permission from ©2013 Elsevier; permission conveyed through RightsLink.)

hydrogen bonds. When embedded in KBr for measuring IR absorption, there may be chemical interaction between GuP and the embedding material that distorts the spectra [161].

#### 11.3.2.5 Thermodynamic Properties of Guanidinium Perchlorate

Because of interference due to the formation of acids during combustion of GuN or GuP in a combustion bomb in a calorimeter, the heat of reaction of guanidinium carbonate with barium perchlorate in solution was measured and used to calculate the enthalpy of formation of GuP [130]. The heats of solution of the various reactants were determined in separate experiments for a wide range of dilutions. The standard enthalpy of formation of solid guanidinium carbonate was taken from other sources ( $-971 \text{ kJ/mol} = -232.2 \text{ kcal/mol}$ ) and served as starting point for the calculations, resulting in a value of  $-310 \pm 2.9 \text{ kJ/mol}$  ( $-74.10 \pm 0.55 \text{ kcal/mol}$ ) for the standard enthalpy of formation of solid GuP and  $40.58 \pm 0.38 \text{ kJ/mol} = 10.416 \pm 0.092 \text{ kcal/mol}$  for the heat of solution of GuP in water. Other sources state an enthalpy of formation of GuP of  $-311.08 \text{ kJ/mol} = -1950 \text{ kJ/kg} = -74.35 \pm 0.22 \text{ kcal/mol} = -466 \text{ cal/g}$  [128, 129], which represents good agreement between the two sets of data.

#### 11.3.3 Chemical Properties of Guanidinium Perchlorate

Guanidinium perchlorate is not as hygroscopic as lithium or magnesium perchlorate. It is soluble in warm water. In spite of the presence of the powerful perchlorate anion, GuP is still slightly under-oxidized, with an oxygen balance of  $-5.0\%$ .

### 11.3.3.1 Thermal Stability of Guanidinium Perchlorate

The thermal decomposition of GuP was investigated by TGA, DTA, MS analysis of volatile decomposition products, and X-ray diffractometry of the crystals [115]. Guanidinium perchlorate undergoes a crystallographic phase transformation at 453 K (180 °C) before melting at 528 K (255 °C). It appears that both the room-temperature and the high-temperature modification crystallize in a cubic lattice. Guanidinium perchlorate decomposes exothermally into gaseous products in the temperature range from 548 to 598 K (275–325 °C). The MS results suggest that the compound undergoes thermal decomposition into neutral particles which are then vaporized, ionized, and oxidized. One of the fragments, cyanamide, was found to undergo trimerization to give melamine. Melamine is thermally very stable (see *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic and Heterocycloaliphatic Amines,” Section 18.4.2).

When GuP is heated at or below 573 K (300 °C) for several hours, it suffers only a very slight loss of weight. Above 673 K (400 °C) ignition occurs, but always after a definite period of inhibition, and with the formation of a yellow solid residue. In the range 573–673 K (300–400 °C), decomposition proceeds at a measurable rate and the reaction goes to completion [156]. The following mechanism was proposed for the decomposition of the salt: (a) Ammonia is evolved, cyanamide and perchloric acid being formed; (b) cyanamide undergoes self-condensation, e.g., to melamine; and (c) these condensation products are oxidized in stages by perchloric acid or ammonium perchlorate to the gaseous products found, amongst them hydrogen chloride, which may eventually combine with ammonia to form ammonium chloride.

Induction periods before ignition at 663–713 K (390–440 °C) were somewhat shorter than the induction periods of AP under similar conditions [171]. The rate constant,  $k$ , for the medium temperature range may be expressed by the equation

$$k = 2.4 \times 10^{11} e^{\frac{-32400}{RT}}$$

where  $k$  is the rate constant in %/min. The temperature dependence of the induction period indicated an activation energy of 127.6 kJ/mol (30.5 kcal/mol). Addition of metal oxide catalysts shortens the induction period and lowers the onset of exotherms. For example, mixtures of GP with CuO, Ag<sub>2</sub>O, Hg<sub>2</sub>O, and MoO<sub>3</sub> exploded at 573, 593, 618, or 618 K (300, 320, 345, or 345 °C), respectively.

DTA thermograms of GuP showed two endotherms and one exotherm [157]. A distinct, reversible endotherm at 453–455 K (180–182 °C) was assigned to a reversible phase transition. This phase transition was also observed in GP/LiClO<sub>4</sub> mixtures. The second endotherm at 521 ± 2 K (248 ± 2 °C) was due to melting. The final exotherm peaking at 665 K (392 °C) was due to decomposition which started at 573 K (300 °C). Other DTA thermograms of GuP reported two exotherms, one at 590 K (317 °C) and another at 623 K (350 °C) [172].

Pure GuP decomposed very slowly at 513–553 K (240–280 °C). The thermal stability of an 80 mass-% AP/20% guanidinium perchlorate mixture was studied by TGA in the temperature range from 523 to 553 K (250–280 °C [162]). Guanidinium perchlorate/AP

mixtures decompose more readily than pure GuP. After a lengthy induction period, the process begins to accelerate rapidly. The temperature dependence of the first-order rate constant (after 5% conversion) can be expressed by

$$k = 10^{12.3} \exp \left[ -41000 \pm \frac{2000}{RT} \right]$$

where  $k$  is the rate constant in  $\text{s}^{-1}$  and  $T$  is the temperature in kelvin.

The qualitative composition of the gaseous products of GuP thermal decomposition and the effect of  $\text{Fe}_2\text{O}_3$  and  $\text{ZnO}$  additives on decomposition were studied by MS [173, 174]. The decomposition of GuP at temperatures 573 K (300 °C) gave  $\text{NH}_4\text{Cl}$ ,  $\text{CO}_2$ ,  $\text{N}_2$ ,  $\text{O}_2$ ,  $\text{N}_2\text{O}$ ,  $\text{NO}$ ,  $\text{NH}_3$ , and  $\text{H}_2\text{O}$ ; while at temperatures 573 K (300 °C),  $\text{NH}_4\text{Cl}$ ,  $\text{CO}_2$ ,  $\text{CO}$ ,  $\text{N}_2$ ,  $\text{NO}$ ,  $\text{O}_2$ ,  $\text{NH}_3$ , and  $\text{H}_2\text{O}$  were formed. Smaller amounts of  $\text{Cl}_2$ ,  $\text{HClO}_4$ ,  $\text{ClO}$ ,  $\text{ClO}_2$ , and  $\text{ClO}_3$  were detected.

The TGA-DTA-DTG thermograms for GuP crystals in a nitrogen atmosphere at a heating rate of 20 °C/min are shown in Figure 13 [161]. Guanidinium perchlorate started to decompose at about 610 K (337 °C). There was no endotherm indicating any loss of water of hydration from the crystal lattice below 573 K (300 °C). Further mass loss occurred in small steps due to the release of volatile substances in the compound, probably ammonia and oxides of chlorine. TGA showed that a complete mass loss took place at near 642 K (369 °C). The endothermic peak at 644.7 K (371.6 °C)

**Figure 13:** DTA, TGA, and DTG thermograms of guanidinium perchlorate decomposition. (Reprinted and modified from [161], with permission from ©2011 Elsevier; permission conveyed through RightsLink.)

occurred at the same temperature as the mass loss in the TGA. Some guanidinium salts emit cold light during thermal decomposition [175].

### 11.3.4 Strand Burning Rates of Guanidinium Perchlorate

Burning rates of formulated solid propellants containing GuP will be discussed in a future set of several volumes on solid propellants and gas generants to be published as part of the *Encyclopedia of Rocket Propellants*. Here we look only at strand burning rates of the pure compound in isolation. The dependence of strand burning rates on pressure was studied for a series of organic perchlorates including GuP in the pressure range 0.1–40 MPa (1–400 atm) [176]. Equations describing burning dependence on pressure were obtained for a systematic series of perchlorates of aliphatic amines, aliphatic polyamines, aromatic amines, amidines, and heterocyclic amines. Organic perchlorates burned several times faster than their nitrate analogs.

### 11.3.5 Safety Properties of Guanidinium Perchlorate

Guanidinium perchlorate was synthesized from guanidinium carbonate and  $\text{HClO}_4$  and its explosive properties were studied [177]. The impact sensitivity was  $\sim 150$  kg-cm (classified grade 6 in Japan Industrial Standard), the BAM friction sensitivity was  $\sim 24$  kg, the ballistic mortar value was 128 (TNT = 100), the decomposition temperature was 653 K (380 °C), and the maximum detonation velocity was 6.3 km/s.

### 11.3.6 Explosive Performance of Guanidinium Perchlorate

Guanidinium perchlorate is a powerful explosive and in the lead block test, the cavity volume expansion was  $400 \text{ cm}^3/10 \text{ g}$ . The detonation velocity was 6000 m/s at a packing density of  $1.15 \text{ g/cm}^3$ , and 7150 m/s at a packing density of  $1.67 \text{ g/cm}^3$  [178]. In the drop-weight sensitivity test, GuP was more sensitive than picric acid. The drop-weight sensitivity in the Bu Mines apparatus was 50 cm with a 2-kg mass (for comparison: picric acid 85 cm under the same conditions).

Guanidinium perchlorate can be synthesized from guanidinium carbonate and dilute perchloric acid. The structure, morphology, thermal decomposition, and thermal stability of guanidinium perchlorate were examined by XRD, elemental analysis, IR spectrometry, scanning electron microscopy (SEM), TGA, and DSC [179]. The XRD and IR spectra of the products were almost identical, regardless of whether the molar ratio of guanidinium carbonate to  $\text{HClO}_4$  was 1 : 2 or 1 : 4. Elemental analysis identified all products as  $\text{CH}_6\text{O}_4\text{N}_3\text{Cl}$ . Guanidinium perchlorate is a relatively insensitive explosive. Its sensitivity is significantly less than that of PETN. With different packing densities, detonation velocities of pure and aluminum-dusted guanidinium perchlorate were about 5500 m/s. The addition of 5 mass-% aluminum powder had little effect on the detonation velocity.

### 11.3.7 Applications of Guanidinium Perchlorate

Guanidinium perchlorate has been evaluated as an ingredient in high-temperature explosives and gas generators for airbag inflation.

The eutectic mixture of GuP and  $\text{LiClO}_4$  is less sensitive than GuP and can be safely used in propellant formulations [164, 165]. The impact sensitivity of a 57.5 GuP + 42.5  $\text{LiClO}_4$  mixture with a melting point of 383 K (110 °C) is 120 cm with a 2-kg mass versus 5 cm for GuP alone.

## 11.4 Other Guanidinium Salts

The stability of the guanidinium ion and its high nitrogen content were the motivation for developing other guanidinium salts with better properties (in some respects, except price) than guanidinium nitrate.

Some guanidinium salts are capable of forming ionic liquids, depending on the anion they are coupled with [180]. Guanidinium dicyanamide and guanidinium octahydrotriborate are ionic liquids melting below 330 K (57 °C).

A double salt of GuN and nitroguanidinium nitrate consists of alternating layers of guanidinium and nitroguanidinium cations, these cations being parallel to each other within the layers and perpendicular in adjacent layers [181]. The layers are connected by  $\text{N}-\text{H}\cdots\text{O}$  hydrogen bonds to nitrate anions, forming an infinite three-dimensional framework. These hydrogen bond patterns are closely related to those of GuN.

### 11.4.1 Guanidinium Dinitramide

Guanidinium dinitramide, guanidinium dinitramide,  $[(\text{NH}_2)_2\text{C}=\text{NH}_2]^+\text{N}(\text{NO}_2)_2^-$ ,  $\text{C}_1\text{H}_6\text{N}_6\text{O}_4$ , GuDN, GDN, CAS RN [170515-96-5], can be prepared by mixing ammonium dinitramide (ADN) and guanidinium chloride in water. However, it is more likely that this reaction would be conducted in the opposite direction as a means to prepare ADN from the less soluble and easily separable GuDN. GuDN melts at 412 K (139 °C), which is substantially higher than the melting point of ADN or HDN, but lower than the melting point of GuN.

In the preparation of ADN, instead of trying to isolate the product as the very soluble ADN, it is easier to isolate the dinitramide salt in the form of the poorly soluble guanidinium dinitramide which precipitates, is filtered, washed, dried, and can later be converted to ADN [182].

Unlike alkali metal dinitramide salts, guanidinium dinitramide does not exhibit abnormal solid-phase decomposition rates. The rates in vacuum and in air are equal, and no increase in the rate is observed at the point of the eutectic melting with guanidinium nitrate (401 K = 128 °C). The rate in the solid state is 400 times slower than in the liquid phase.

Guanidinium dinitramide melts at 421 K (148 °C) [116]. Other sources give a melting point of 417 K (144 °C) [183].

Guanidinium dinitramide (GuDN) was prepared by mixing ADN and guanidinium chloride in water. The thermal behavior of GuDN was studied under non-isothermal conditions by DSC and TGA/DTG [184]. The apparent activation energy ( $E_{\text{act}}$ ) and the pre-exponential constant ( $A$ ) of the exothermic decomposition reaction of GuDN were 118.75 kJ/mol and  $10^{10.86} \text{ s}^{-1}$ , respectively. The critical temperature of thermal explosion ( $T_b$ ) of GuDN was 437 K (164 °C). The heat capacity of GuDN was determined by the micro-DSC method, and the molar heat capacity was  $234.76 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$  at 298.15 K. The adiabatic time-to-explosion of GuDN was estimated to be somewhere between 405 and 455 s (but this depends on the surface: volume ratio of the sample container!).

Guanidinium dinitramide crystallizes in the triclinic space group with cell dimensions  $a = 8.325(2) \text{ \AA}$ ,  $b = 9.301(2) \text{ \AA}$ ,  $c = 9.868(2) \text{ \AA}$ ,  $\alpha = 84.73(3)^\circ$ ,  $\beta = 69.25(3)^\circ$ ,  $\gamma = 67.55(3)^\circ$ , while hydroxyguanidinium dinitramide crystallizes in the non-centric monoclinic space group  $Pc$  with cell dimensions  $a = 7.098(2) \text{ \AA}$ ,  $b = 3.5160(10) \text{ \AA}$ ,  $c = 14.358(3) \text{ \AA}$ ,  $\beta = 98.940(10)^\circ$  [185]. The structures contain protonated amine cations and dinitramide anions linked by hydrogen bonding. In both structures the conformations adopted by the dinitramide anions can be related to the types of hydrogen bonds it forms with the surrounding amine cations.

Guanidinium dinitramide was prepared by mixing ammonium dinitramide and guanidinium chloride in water, and its structure was determined by single-crystal XRD [186]. The crystal is triclinic, space group  $P1$ , with crystal parameters of  $a = 0.8332(5) \text{ nm}$ ,  $b = 0.9306(6) \text{ nm}$ ,  $c = 0.9878(6) \text{ nm}$ ,  $\alpha = 84.659(11)^\circ$ ,  $\beta = 69.213(12)^\circ$ ,  $\gamma = 67.451(12)^\circ$ ,  $V = 0.6605(7) \text{ nm}^3$ ,  $Z = 4$ , and  $D_{\text{calc}} = 1.671 \text{ g/cm}^3$ . Based on DSC and TGA/DTG results, its thermal decomposition process takes place in four stages, where the third stage is an intense exothermic decomposition process. The apparent activation energy and pre-exponential constant of the exothermic decomposition reaction are 118.75 kJ/mol and  $10^{10.86} \text{ s}^{-1}$ , respectively. The critical temperature of thermal explosion is 437 K (164 °C). GuDN has a better thermal stability than ADN.

Enthalpies of formation and solution of guanidinium, aminoguanidinium, and triaminoguanidinium salts of nitric and dinitramidic acids were determined by combustion and solution calorimetry methods [131]. The enthalpies of formation of the respective cations by themselves in infinitely diluted aqueous solution were then calculated using the known enthalpy of formation of the nitrate ion ( $-206.8 \text{ kJ/mol} = -49.44 \text{ kcal/mol}$ ). The upper heats of combustion in a constant volume calorimetric bomb, the enthalpies of formation, and the enthalpies of solution of guanidinium, aminoguanidinium, and triaminoguanidinium dinitramide are summarized in Table 13. Of all the compounds studied in this paper, triaminoguanidinium dinitramide is the only one with a positive enthalpy of formation.

The thermal decomposition of GuDN was studied under non-isothermal conditions by DSC and TGA/DTG [184]. The apparent activation energy ( $E$ ) and pre-

**Table 13:** Heats of combustion, enthalpies of formation, and enthalpies of solution of guanidinium and mono- and triaminoguanidinium dinitramides.

Data source: [131]

exponential constant ( $A$ ) of the exothermic decomposition stage of GuDN were 118.75 kJ/mol and  $10^{10.86} \text{ s}^{-1}$ , respectively. The critical temperature of thermal explosion of GuDN was 437 K (164 °C). The standard molar heat capacity was  $234.76 \text{ J} \cdot \text{mol}^{-1} \cdot \text{K}^{-1}$  at 298 K.

Other reported data for the enthalpy of formation of guanidinium dinitramide are remarkably similar: -168 kJ/mol (-40.1 kcal/mol) as reported by [44], and -169 kJ/mol (-40.7  $\pm$  1.5 kcal/mol; meas.) as reported by [187].

Guanidinium dinitramide can be synthesized from guanidinium carbonate. When using this method, two different crystalline forms ( $\alpha$ -type and  $\beta$ -type) may be obtained depending on the type of applied solvents and synthesis and recrystallization conditions [188]. During crystallization, water might become trapped in a crystal lattice between inner molecules. Despite having the same chemical composition, Raman IR and TGA-DSC revealed different physical characteristics of the two forms. Peaks of Raman shift near  $1000 \text{ cm}^{-1}$  implied different chemical structures. The  $\beta$ -type is thermally more stable than the  $\alpha$ -type. Thermal analysis revealed an exotherm peak temperature of 428.8 K (155.7 °C) for  $\alpha$ -type but one of 464.7 K (191.6 °C) for  $\beta$ -type. The exotherm heat release caloric value of  $\alpha$ -type was 536.4 J/g, which was 2.5 times smaller than that of the  $\beta$ -type, which was 1310 J/g. While the synthesized GDN of  $\alpha$ -type showed a steep exothermic decomposition, the  $\beta$ -type decomposed slowly after melting through an endothermic process. This implied that despite the same molecular structural formula, some different thermal properties are obtained depending on synthesis conditions.

Five different types of guanidinium dinitramide (GuDN-I, II, III, IV, V) were synthesized using different starting materials such as guanidinium acetate, chloride, carbonate, nitrate, or sulfate [189]. Intermediates and products formed in these processes were identified and their thermal properties and chemical structures were examined. The absorption peaks measured by FTIR were assigned to guanidinium ion (3452, 3402, 3354, 3278,  $1642 \text{ cm}^{-1}$ ) and to dinitramide ion (3208, 1570, 1492,

1416, 1337, 1179, 1000  $\text{cm}^{-1}$ ). The activation energies of GuDN thermal decomposition determined by DTA from exothermic reactions at above 426 K (153 °C) differed only very little:  $E_a = 222.8 \text{ kJ/mol} = 53.26 \text{ kcal/mol}$  (GuDN-I),  $213.1 \text{ kJ/mol} = 50.94 \text{ kcal/mol}$  (GuDN-II),  $219 \text{ kJ/mol} = 52.34 \text{ kcal/mol}$  (GuDN-III),  $260.2 \text{ kJ/mol} = 62.19 \text{ kcal/mol}$  (GuDN-IV),  $231.4 \text{ kJ/mol} = 55.32 \text{ kcal/mol}$  (GuDN-V). See also [190–192].

#### 11.4.2 Guanidinium Nitroformate

Although several energetic salts containing the nitroformate anion have been reported in the literature, so far only one compound, hydrazinium nitroformate, HNF, has gained practical application. Since its discovery in 1951, as of 2006, more than 80 publications have since appeared, showing that there is continued interest in investigating the properties and new applications of HNF. Along the same line of investigation, guanidinium nitroformate monohydrate (GNFH), aminoguanidinium nitroformate (AGNF), diaminoguanidinium nitroformate (DAGNF), and triamino-guanidinium nitroformate (TAGNF) have been prepared and characterized [193–195]. The following abbreviations are used for the four compounds:

Abbreviations used: GNFH AGNF DAGNF TAGNF

GNFH:  $\text{R1} = \text{R2} = \text{R3} = \text{H}$  plus  $\text{H}_2\text{O}$

AGNF:  $\text{R1} = \text{NH}_2$ ,  $\text{R2} = \text{R3} = \text{H}$

DAGNF:  $\text{R1} = \text{R2} = \text{NH}_2$ ,  $\text{R3} = \text{H}$

TAGNF:  $\text{R1} = \text{R2} = \text{R3} = \text{NH}_2$

Guanidinium nitroformate was obtained according to the literature procedure as the monohydrate (GNFH), whereas AGNF, DAGNF, and TAGNF were obtained as the water-free species and were reported for the first time in 2006. Guanidinium nitroformate crystallized from aqueous solutions with one molecule of water as hydrate  $\text{C}_2\text{H}_6\text{N}_6\text{O}_6 \cdot \text{H}_2\text{O} = \text{C}_2\text{H}_8\text{N}_6\text{O}_7$ . This may explain the different melting points given for guanidinium nitroformate, with the hydrate melting point listed as 383–390 K (110–117 °C) and the anhydrous salt supposedly melting at 401 K (128 °C). All of the compounds were obtained as bright yellow solids in high yields by the reaction of either the potassium or silver salt of nitroform with the corresponding guanidinium chloride in acetonitrile. All four compounds and melamine nitroformate have been characterized using single-crystal XRD (Table 14) as well as multi-nuclear NMR spectroscopy, IR and Raman spectroscopy, MS, DSC (at five different heating rates), and elemental analysis.

**Table 14:** Crystal structure and physical properties of guanidinium nitroformates.

| Parameter                          | GNFH                                                        | AGNF                                                        | DAGNF                                                       | TAGNF                                                       |

<sup>a</sup> GOOF = goodness of fit

Data source: [193]

Infrared and Raman spectra of the four (amino)guanidinium nitroformates were measured and tabulated, also in comparison to spectra obtained from ANF, HNF, and melamine nitroformate (Table 15). The <sup>1</sup>H, <sup>13</sup>C, and <sup>15</sup>N NMR shifts of all of these salts are also available.

The sensitivity properties of GNFH, AGNF, DAGNF, and TAGNF were measured in order to establish safe handling procedures for these compounds in comparison to HNF. Two different instruments were used to determine the friction and impact sensitivity: the Bundesanstalt für Materialforschung und Prüfung (BAM) drop hammer (BAM fh [Fallhammer]) and friction tester (BAM ft). In the series of increasing nitrogen content from GNFH to TAGNF, the materials became more sensitive to impact and friction. GNFH was found to meet the criteria of the United Nations (UN) Recommendations for the Transport of Dangerous Goods, with a friction sensitivity of greater than 360 N and an impact sensitivity of greater than 29.6 J (1 J = 1 Nm). In contrast, great care should be taken when handling the other salts, which are considerably more sensitive: In the series of increasing nitrogen content from GNFH to TAGNF, the materials became more sensitive to impact and friction. The sensitivity of TAGNF was about the same as that of dry HNF (Table 16).

Table 15: IR and Raman spectra of four (amino)guanidinium nitroformates.

| GNFH                                                                                                                                                                                                                                          |                                                                                                                                                                                                                      | AGNF                                                                                                                                                                                                                                        |                                                                                                                                                                                                                                                            | DAGNF                                                                                                                                                                                                                                                                  |                                                                                                                                   | TAGNF                                                                                                                                                                                                             |                                                                                                                                                                                          |

Data source: [193]

The onset and point of maximum thermal decomposition of the five salts were monitored using differential scanning calorimetry. Thermal stability improved in the sequence AGNF DAGNF TAGNF. A good example for the effect of different heating rates on the shape of the thermograms of aminoguanidinium nitroformate is shown in Figure 19 (in section “Aminoguanidinium Nitroformate”).

Guanidinium trinitromethanide (nitroformate) monohydrate has been obtained from guanidinium chloride and either potassium trinitromethanide or iodotrinitromethane [196]. Guanidinium dinitromethanide was also prepared in a metathetical reaction from guanidinium nitrate and sodium dinitromethanide [197]. Guanidinium, triazolium, and tetrazolium dinitromethanide salts are thermally stable and can be relatively insensitive to impact [198].

#### 11.4.3 Guanidinium Salts of Other Nitrogen-Rich Acids

As a general rule in organizing the overwhelming amount of information on nitrogen-rich salts derived from guanidine, aminoguanidine, diaminoguanidine, and triaminoguanidine, we have attempted to sort the salts by the cation first, followed by a list of the anions. There are several exceptions to this rule, e.g., if the common denominator of a publication is the evaluation of one anion paired with several cations. Properties that make salts useful as propellant ingredients may come from either cation or anion or both. There is a substantial amount of overlap between the current sections on guanidinium salts and salts formed with heterocyclic anions. For instance, information on triaminoguanidinium 5,5'-azotetrazolate (TAGZT) can be found here and in *Encyclopedia of Liquid Fuels*, chapter “Heterocyclic and Heterocycloaliphatic Amines.”

#### 11.4.4 Guanidinium Salts of Aromatic Nitrogen-Rich Acids

Picric acid and styphnic acid are often used for the characterization of organic amines, including guanidine derivatives, because these salts are relatively insoluble and well crystallized. However, some of these salts are impact and friction sensitive to the point that some people have considered them as primary explosives. The sensitivity and thermal stability data of picrates and styphnates of guanidine and guanidine derivatives are summarized in Table 17, 18, and 19. For an organic energetic compound, the high melting point of guanidinium picrate is remarkable. It is not likely that any of these will find applications as ingredients in rocket propellants.

**Table 17:** Impact sensitivity of guanidinium styphnates and picrates.

| Compound                                                       | Impact sensitivity <sup>a</sup> , 50% height, mm |
|----------------------------------------------------------------|--------------------------------------------------|
| Hydrazinium(1+) styphnate                                      | 200                                              |

#### 11.4.5 Guanidinium Salts of Aliphatic Nitrogen-Rich Acids

Two modifications of guanidinium dicyanamide  $[\text{C}(\text{NH}_2)_3][\text{N}(\text{CN})_2]$  were obtained by ion-exchange reactions in aqueous or methanolic solutions [200]. The hygroscopic compounds were characterized by NMR, MS, and vibrational spectroscopy. The single-crystal XRD crystal structures were  $\beta$ - $[\text{C}(\text{NH}_2)_3][\text{N}(\text{CN})_2]$ :  $Pna2_1$ ,  $Z = 8$ ,  $a = 1373.1(3)$ ,  $b = 495.5(1)$ ,  $c = 1802.9(4)\text{pm}$ ,  $V = 1226.7(4)\text{pm}^3$ ;  $\alpha$ - $[\text{C}(\text{NH}_2)_3][\text{N}(\text{CN})_2]$ :  $P2_1/c$ ,  $Z = 8$ ,  $a = 1924.9(4)$ ,  $b = 496.0(1)$ ,  $c = 1372.4(3)\text{pm}$ ,  $\beta = 110.46(3)^\circ$ ,  $V = 1227.5(4)\text{pm}^3$ . The structures were largely equivalent in terms of the overall assembly of the molecular ions. The polymorphs showed a succession of thermal events in the temperature region between 240 and 440 K when examined by temperature-dependent XRD and TGA. Due to the chemical composition of guanidinium dicyanamide ( $\text{C}_3\text{N}_6\text{H}_6$ ), which is formally identical to that of melamine  $\text{C}_3\text{N}_3(\text{NH}_2)_3$ , and its thermal reactivity, which leads to melamine at around 400 K, guanidinium dicyanamide may be suited as a molecular precursor for synthesis of graphitic carbon nitride.

Guanidinium, aminoguanidinium, diaminoguanidinium, and triaminoguanidinium dicyanamides have been evaluated as ionic liquids and hypergolic fuels. Ionic liquids derived from combinations of alkylammonium, hydrazinium, guanidinium, and hydrazidinium cations with dicyanamide anions were tested for their reactivity toward hypergolic oxidizers [201]. Table 20 is a summary of properties of guanidinium dicyanamides.

**Table 20:** Properties of guanidinium dicyanamides.

#### 11.4.6 Guanidinium Salts of Heterocyclic Nitrogen-Rich Acids

Guanidinium salts of heterocyclic acidic compounds are promising propellant and gas generant ingredients because they are often the thermally most stable in a group of salts tested for thermal stability. Guanidine is a strong base and forms stable salts with many proton donors, even with weak proton donors. The following heterocyclic guanidinium salts are arranged in order of increasing nitrogen atoms in the ring, starting with triazoles and continuing with tetrazoles.

##### 11.4.6.1 Guanidinium 4,5-Dicyano-2*H*-1,2,3-Triazoles

The ammonium, guanidinium, aminoguanidinium, diaminoguanidinium, and triaminoguanidinium salts of the 4,5-dicyano-1,2,3-triazolate anion were prepared by metathetical reactions from the corresponding ammonium and guanidinium halides with the silver salt of 4,5-dicyano-1,2,3-triazole and spectroscopically characterized by  $^1\text{H}$  and  $^{13}\text{C}$  NMR, IR, and Raman, and the thermal stabilities investigated using DSC [202]. The solid-state crystal structures determined using single-crystal XRD are summarized in Table 21. The impact and friction sensitivities of these compounds were investigated, and all compounds were found to be neither impact (30 J) nor friction sensitive (360 N).

##### 11.4.6.2 Guanidinium 5-Aminotetrazolate

Guanidinium 5-aminotetrazolate (GA, GAT, GZT) has been evaluated as a gun propellant additive that reduces barrel wear and muzzle flash. Guanidinium 5-aminotetrazolate (GA) can be prepared by the simple reaction of guanidinium carbonate and 5-amino-1*H*-tetrazole monohydrate in ethanol. The basicity of guanidinium carbonate suffices for the abstraction of a proton in the 5-aminotetrazole ring. After only 30 min reaction time, the final product can be obtained with a yield of 95% after one reaction step [203]. The standard enthalpy of formation, measured by combustion calorimetry, is +85.9 kJ/mol. The IR spectrum of GA in Figure 14 is dominated by the N–H stretch and deformation vibrations of the amine groups ( $\nu = 3426, 3337, 3184, 1662, 1519 \text{ cm}^{-1}$ ) and the absorption bands of the tetrazole fragment ( $\nu = 1561, 1136, 1105, 1001 \text{ cm}^{-1}$ ).

In the DSC thermogram of GA with a heating rate of 0.5 K/min under argon atmosphere, one can see a melting point at 397.2 K and the peak area translates into a melting enthalpy of 26.5 kJ/mol (Figure 15).

The thermal decomposition of guanidinium 5-aminotetrazolate was evaluated in comparison to GuN, TAGN, and five other nitrogen-rich additives [203, 204]. The TGA-DTA curve for guanidinium 5-aminotetrazolate showed an endothermic melting at 397 K (124 °C), followed by a four-stage, stepwise weight-loss sequence (Figure 16). The first stage corresponded to weak exothermic decomposition observed in the simultaneous DTA between 423 and 505 K (150 and 232 °C); the second and third stages also corresponded to weak exothermic decomposition within the temperature range of 505 to 631 K (232 to 358 °C), accompanied by 15 and 11.6% weight loss, respectively; and the fourth stage corresponded to an endothermic decomposition between 631 and 833 K

Table 21: Crystal structures of 4,5-dicyano-1,2,3-triazolate salts of several nitrogen bases.

| Compound                                         | Family       | Space group           | Cell structure parameters |             |             |             |                     | Z  |

(358 and 560 °C), corresponding to 44.1% weight loss. The identification of the decomposition gases by FTIR and GC-MS allowed evaluation of the chemical processes during the thermal degradation of guanidinium 5-aminotetrazolate, and identified  $\text{HN}_3$ ,  $\text{NH}_3$ , and  $\text{H}_2\text{N}-\text{CN}$  as the decomposition gases evolved in the first, second, and third stages of the decomposition process, respectively.

Decomposition products identified by IR were hydrogen azide  $\text{HN}_3$ , ammonia  $\text{NH}_3$ , and cyanamide  $\text{H}_2\text{N}-\text{CN}$  at higher temperatures. The thermal decomposition of GA is initiated by the ring opening of the heterocyclic tetrazole structure. The release of hydrogen azide is typical for the thermolysis of substituted 5-aminotetrazole.

An investigation of the molecular and electronic structures of GA showed that the ion pair  $[\text{C}(\text{NH}_2)_3]^+ \cdots [\text{CN}_5\text{H}_2]^-$  forms two planes with the planar ions parallel at a distance of 1.8 Å [205]. A CNDO/2 approximation of the MO method was used for calculating the equilibrium distance, the charge separation, and the electron distribution, and for examining the possible role of hydrogen bonding in the crystal lattice.

Physical properties of GA and several other 5-aminotetrazolate salts as reported by Tao et al. [206] are summarized in the chapter “Heterocyclic and Heterocycloaliphatic Amines.”

A detailed reaction mechanism for the decomposition of GA consisting of 55 species and 85 elementary chemical reactions was formulated based on quantum chemical calculations with insight from experiments [207, 208].

Numerical simulation of the GA and GA/RDX decomposition process was carried out by solving a system of ordinary differential equations representing the mass loss, reversible reactions, and evaporation of stable species. Simulation results were found to satisfactorily match the experimental data of Neutz et al. [203]. Within the present modeling framework and assumptions, the following major conclusions were obtained:

1. Decomposition of GA begins with chemical interaction within the ion pair  $\text{Gu}^+$  and  $5\text{ATz}^-$ , where the carbon in  $\text{Gu}^+$  bonds to a ring nitrogen adjacent to the carbon in  $5\text{ATz}^-$ , forming an intermediate INT5.
2. The pathway in which the intermediate species INT5 is formed is the most critical step.
3. The first step observed in mass loss is caused by formation and evaporation of  $\text{NH}_3$ ,  $\text{HN}_3$ ,  $\text{N}_2$ , and  $\text{H}_2\text{NCN}$ , whereas melamine evaporation results in the second step.
4. Decomposition at first proceeds through endothermic reactions, but is later replaced by exothermic reactions producing  $\text{N}_2$ ,  $\text{NH}_3$ , and  $\text{HN}_3$ .
5. Proton transfer between  $\text{Gu}^+$  and  $5\text{ATz}^-$  is not predicted to occur by the quantum mechanics calculations for the liquid phase.

#### 11.4.6.3 Guanidinium 1,5'-bis-1*H*-Tetrazolates

The thermal decomposition behavior of the guanidinium salt of 1,5-bis-1*H*-tetrazole was analyzed by TG-DTA-MS [209]. The combustion behavior of  $\text{CuO}$ /guanidinium 1,5'-bis-1*H*-tetrazolate mixtures was examined for varying O/F mixture ratios [210–213].

#### 11.4.6.4 Guanidinium Azotetrazolate

Guanidinium azotetrazolate, GAT, GZT,  $\text{GAzT}$ ,  $\text{GUZT}$ ,  $\text{C}_4\text{H}_{12}\text{N}_{16}$ , is a unique energetic material with good thermal stability and an exceptionally high nitrogen content (79 mass-% nitrogen).

Ammonium, guanidinium, and triaminoguanidinium azotetrazolate (AAZ, GAZ, and TAGAZ) were synthesized starting with sodium azotetrazolate pentahydrate [214].

For comparison, the reported heats of formation for ammonium (AAZ), guanidinium (GAZ), and triaminoguanidinium azotetrazolate (TAGAZ) salts are +410, +443, and +1075 kJ/mol (+98, +106, and +257 kcal/mol), respectively. The density of GAZ is 1.54 g/cm<sup>3</sup> and the enthalpy of formation is +410 kJ/mol (+98 kcal/mol).

The maxima of the melting endotherm for AAZ, GAZT, and TAGAZ in the DSC were at 485, 477, and 532 K (212, 204, and 259 °C), respectively [215]. The onsets of thermal decomposition in the TGA were at 453, 473, and 523 K (180, 200, and 250 °C), respectively. TAGAZ has the highest positive heat of formation of the three salts investigated, +1075 kJ/mol (+257 kcal/mol). Triaminoguanidinium azotetrazolate (TAGAZ) was incorporated into solid propellant formulations and DSC results indicated that it does not have any adverse effect on thermal stability of a double-base matrix. The burning rate data indicated that TAGAZ acts as an efficient energetic additive in composite-modified double-base (CMDB) propellant formulations in the high-pressure region. Guanidinium azotetrazolate has been evaluated as an additive to gun propellants to reduce barrel wear.

Guanidinium azotetrazolate (GAzT) was evaluated as an additive for a high-regression-rate fuel mixture with hydroxyl-terminated polybutadiene (HTPB) [216]. GAzT was found to react with N100, a common curative for HTPB, and a test grain made with N100, HTPB, and GAzT formed a foam about one and a half times its original volume. An alternative isocyanate curative was found, polyisocyanate (PAPI), with which it did not react.

As shown in Figure 17, the TGA curve of guanidinium azotetrazolate (GAzT) at a heating rate of 2°/min consisted of a two-stage weight-loss process [204]. The first stage indicated the exothermic rapid reaction also observed in the parallel DTA between 473 and 532 K (200 and 259 °C), resulting in a 59% weight loss, and the second stage corresponded to a slow endothermic reaction observed beyond 532 K (259 °C). The first stage is the result of the heterocyclic ring opening, which involved abstraction of the acidic protons available in the guanidinium cation by the azotetrazolate anion, which leads to the formation of a highly unstable azotetrazolate cation and subsequent opening of the azotetrazolate ring with the release of molecular nitrogen and cyanamide.

The thermal decomposition of guanidinium azotetrazolate (GAzT) was studied by TGA and DSC [217]. Based on the *in situ* analysis of products in condensed and gas phases by a combination of hot-stage with rapid-scan FTIR spectroscopy and pyrolysis gas chromatography mass spectrometry (Py-GC-MS), a thermal decomposition mechanism of GAzT was proposed. Results showed that the first mass loss is caused by an exothermic decomposition reaction of azotetrazolate and the endothermic decomposition reaction of guanidinium. An intermediate product, tetrazole azide (CHN<sub>7</sub>), may form through a ring-opening reaction of one tetrazole on the azotetrazolate molecule.

Additional work analyzed the decomposition of guanidinium azotetrazolate (GAzT) in the liquid phase by a combined experimental and computational approach

**Figure 17:** DTA-TGA Thermogram of guanidinium azotetrazolate decomposition. (Republished and modified from [204], with permission of ©2009 American Institute of Aeronautics Astronautics; permission conveyed through Copyright Clearance Center Inc.)

using FTIR spectroscopy to acquire the spectral transmittance of the evolved gas-phase species from rapid thermolysis as well as time-of-flight mass spectrometry (ToFMS) to acquire mass spectra of the evolved gas-phase species [218]. Sub-milligram samples of GAzT were heated at rates of about 2000 K/s to a pre-set temperature (553–573 K), at which decomposition occurred under isothermal conditions.  $N_2$ ,  $NH_3$ , HCN, guanidine, and melamine were identified as products of decomposition.

TGA analyses showed that GAzT loses about 62.2% mass between 522 and 531 K (249–258 °C) [219]. See also [220].

Guanidinium azotetrazolate was prepared by a replacement reaction using guanidinium nitrate and 5-amino-tetrazole as raw materials [221, 222]. The morphology and structure of GAzT were characterized by SEM, FTIR, and elemental analysis. Thermal decomposition of GAzT was investigated by TGA, DSC, condensed-phase thermolysis/rapid-scan FTIR, and pyrogenetic MS in a temperature-programmed mode. The thermal decomposition onset temperature was 529 K (256 °C).

A numerical simulation of the GuzT decomposition process was carried out by solving a system of ordinary differential equations representing the mass loss, reversible reactions, and evaporation of stable species [223, 224]. A detailed reaction mechanism for the decomposition of GuzT consisting of 76 species and 107 elemen-

tary chemical reactions was validated. Simulation results were found to satisfactorily match the experimental data reported by An [221]. The major conclusions were:

1. Decomposition of GuZT begins with the ring opening of  $AzT^{2-}$  to release  $N_2$ , forming the intermediate INT4.
2. A pathway in which the intermediate species INT4a and guanidine are formed is the most critical step, as all the major product species are sensitive to this pathway.
3. The first step observed in mass loss is caused by formation and evaporation of  $NH_3$ ,  $N_2$ , and  $HCN$ , whereas melamine evaporation results in a second step.
4. Decomposition proceeds through exothermic reactions throughout the event, producing  $N_2$ ,  $NH_3$ , and  $HCN$ .

#### 11.4.6.5 Other Guanidinium Salts of Heterocyclic Acids

The guanidinium, ethylenediammonium(2+), ammonium, and hydrazinium(1+) salts of 3-nitro-1,2,4-triazol-5-one (NTO) were synthesized and characterized [225]. Small-scale sensitivity tests indicated that these compounds are thermally stable and only moderately insensitive to impact.

The guanidinium salt of *N*-nitro-*N'*-1*H*-tetrazol-5-yl-guanidine,  $C_3H_9N_8O_2$ ,  $M=189.16$  g/mol, has been prepared and patented as an additive to double-base propellants [226]. It melts at 509–513 K (236–240 °C).

Guanidinium salt of *N*-nitro-*N'*-1*H*-tetrazol-5-yl-guanidine

#### 11.4.6.6 Other Guanidinium Salts with Substituents on the Guanidine Molecule

Energetic salts based on substituted guanidinium cations containing a picryl moiety, *N*-(2,4,6-trinitrobenzylideneamino)guanidinium cation, were synthesized and characterized by IR and multi-nuclear NMR spectroscopy, DSC, TGA, elemental analysis, and single-crystal XRD [227]. Most of the salts decomposed at temperatures above 180 °C, exhibited low impact sensitivities (20–40 J), low friction sensitivities (220–340 N), and were insensitive to electrostatic discharge (ESD). The predicted detonation velocities ranged from 7842 to 8394 m/s.

## 12 Aminoguanidine

Aminoguanidine,  $\text{H}_2\text{NNHC(=NH)NH}_2$ ,  $\text{C}_1\text{N}_4\text{H}_6$ , hydrazinecarboximidamide, guanylhypurazine, CAS RN [79-17-4], is prepared by reaction of cyanamide and hydrazine hydrate.

It is available in industrial quantities in the form of its bicarbonate salt, which is prepared by treating a cyanamide solution with hydrazine hydrate and simultaneously bubbling through an excess of carbon dioxide [228, 229]. Free aminoguanidine is rarely used as such. It is mostly used in the form of one of its salts. Several aminoguanidinium salts have already been discussed or will be discussed in sections where they were compared to similar salts derived from guanidine or triaminoguanidine. All of these salts are good sources of nitrogen in solid gas generants.

Aminoguanidine is a starting material in making tetracene, a primary explosive (see chapter “Heterocyclic and Heterocycloaliphatic Amines”). A method for analyzing trace amounts of aminoguanidine was necessary to characterize the conversion from aminoguanidine to tetracene and to detect any unreacted aminoguanidine in the waste solution from the preparation process of tetracene. Aminoguanidine is not an electroactive species in polarographic determinations. However, some compounds containing hydrazine groups can become an electroactive species by reacting them with sodium nitrate or acetone in acidic solution. An electroactive species was produced from aminoguanidine by reacting with sodium nitrite or acetone in acidic solution, and aminoguanidine in the solution could be analyzed by polarography [230].

### 12.1 Aminoguanidinium Nitrate

Aminoguanidinium nitrate, monoaminoguanidinium nitrate; hydrazinecarboximidamide, nitrate (1:1); AGN, MAGN,  $\text{C}_1\text{H}_7\text{N}_5\text{O}_3$ , molecular mass 137.1 g/mol, nitrogen content 51.08% N, oxygen balance -29.2, CAS RN [10308-82-4], forms colorless crystals that melt at 417–419 K (144–146 °C) and are soluble in water or ethanol. For the heats of combustion, enthalpies of formation, and enthalpies of solution of (mono)aminoguanidinium nitrate, see Table 10. The IR spectrum of aminoguanidinium nitrate is shown in Figure 18.

Monoaminoguanidinium nitrate melts at 417.6–418.6 K (144.5–145.5 °C) and in the DTA the maxima of two exotherms are at 523 and 563 K (250 and 290 °C).

Aminoguanidinium nitrate crystallizes in triclinic crystals in space group  $P\bar{1}$ , and the cell parameters are  $a = 7.341 \text{ \AA}$ ,  $b = 7.722 \text{ \AA}$ ,  $c = 6.024 \text{ \AA}$ ,  $\alpha = 110.47^\circ$ ,  $\beta = 102.64^\circ$ ,  $\gamma = 104.87^\circ$ ,  $V = 290.7 \text{ \AA}^3$ ,  $Z = 2$ ,  $\rho_{\text{XRD}} = 1.566 \text{ g/cm}^3$  [231]. The oxygen atoms of the nitrate

**Figure 18:** IR Spectrum of aminoguanidinium nitrate. (Reproduced and modified from [125], with permission from Levering Estate.)

ions in aminoguanidinium nitrate are connected by hydrogen bonds to the hydrogen atoms in the aminoguanidinium ions.

Similar results were obtained with aminoguanidinium nitrate that was prepared through the reaction of aminoguanidinium bicarbonate and nitric acid solution. The crystal structure of MAGN was determined by single-crystal XRD [232]. The result showed that there is no double bond in the compound and that it is a typical nitrate. The crystal is triclinic with space group  $P\bar{1}$ ,  $a = 0.6028(1)\text{nm}$ ,  $b = 0.7344(1)\text{nm}$ ,  $c = 0.7723(1)\text{nm}$ ;  $\alpha = 104.850(10)^\circ$ ,  $\beta = 110.450(10)^\circ$ ,  $\gamma = 102.660(10)^\circ$ ;  $V = 0.2911(7)\text{nm}^3$ ,  $Z = 2$ ,  $\rho_{\text{XRD}} = 1.564\text{g/cm}^3$ .

The Cu-complex nitrate of aminoguanidine  $\text{Cu}[\text{HN}=\text{C}(\text{NH}_2)(\text{NHNH}_2)](\text{NO}_3)_2$  was synthesized as a potential new gas generant, and the thermal decomposition behavior was investigated [233]. During the isothermal decomposition reaction at 374–398 K (101–125 °C), the complex formed a stable intermediate. The activation energy of the reaction was 51 kJ/mol. Above 398 K (125 °C), the Cu-complex nitrate of aminoguanidine decomposed so rapidly that ignition occurred. The linear burning rate of a stoichiometric mixture with  $\text{Sr}(\text{NO}_3)_2$  as the oxidizer was 6.48 mm/s and the flame temperature was 1616 K (1343 °C).

The enthalpy of formation of monoaminoguanidinium nitrate in comparison to GuN and other nitrates is listed in Table 10. Additional data were published for the enthalpy of formation of monoaminoguanidinium nitrate:  $\Delta H_f^{298} = -278.7 \pm 0.7\text{kJ/mol} = -66.62 \pm 0.18\text{kcal/mol}$  [234, 235].

## 12.2 Aminoguanidinium Perchlorate

Aminoguanidinium perchlorate,  $\text{CH}_7\text{N}_4\text{ClO}_4$ ,  $\text{AGClO}_4$ , aminoguanidine perchlorate; CAS RN [41195-24-8]; hydrazinecarboximidamide, monoperchlorate; can be formed by the reaction of aminoguanidinium bicarbonate (which is readily available) with aqueous perchloric acid solution [5].  $\text{AGClO}_4$  (not to be confused with silver perchlorate,  $\text{AgClO}_4$ ) melts at 345 K (72°C) and is the most stable of three similar compounds and begins to decompose at 523 K (250°C). It is thermally more stable than  $\text{TAGClO}_4$ . The structure of  $\text{AGClO}_4$  in the crystalline state was determined using low-temperature single-crystal XRD, indicating a monoclinic structure. The crystallographic data of aminoguanidinium, triaminoguanidinium, and azidoformamidinium perchlorate are summarized in Table 22.

Further information regarding the crystal structure determinations have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers listed in Table 22. The enthalpy of formation of  $\text{AGClO}_4$  is  $-161 \pm 7$  kJ/mol. The impact sensitivity of  $\text{AGClO}_4$  as tested in the BAM fall hammer machine was 4 N m, and the friction sensitivity was 110 N. It is less sensitive than  $\text{TAGClO}_4$ .

Other data for the enthalpy of formation of monoaminoguanidinium perchlorate derived from the enthalpy of solution in infinitely diluted solution gave  $\Delta H_f^{298}(\text{S}) = -191.96 \pm 0.87$  kJ/mol =  $-45.88 \pm 0.21$  kcal/mol [234].

**Table 22:** Crystallographic data of aminoguanidinium, triaminoguanidinium, and azidoformamidinium perchlorate.

Data source: [5]

### 12.3 Aminoguanidinium Dinitramide

Aminoguanidinium dinitramide, aminoguanidinium dinitramide, aminoguanidine dinitramide,  $[\text{H}_2\text{NC}(=\text{NH})\text{NHNH}_3^+][\text{N}(\text{NO}_2)_2^-]$ , melts at 367 K (94 °C) [131]. Other sources give the same melting point of 367 K (94 °C) [116, 236].

For the heats of combustion, enthalpies of formation, and enthalpies of solution of (mono)aminoguanidinium dinitramide, see Table 13. Other sources gave an enthalpy of formation of aminoguanidinium dinitramide as  $-48 \text{ kJ/mol}$  ( $-11.5 \text{ kcal/mol}$ ) [44].

### 12.4 Aminoguanidinium Nitroformate

Aminoguanidinium nitroformate,  $[\text{H}_2\text{NC}(=\text{NH})\text{NHNH}_3^+][\text{C}(\text{NO}_2)_3^-]$  is one of four guanidine-derivative nitroformate compounds prepared and characterized by a group of researchers at the University of Munich in Germany [193, 195]. The properties are summarized in Tables 14 and 15 above. Here, one of the several images from the poster was selected as an example of the influence of heating rate on the shape of thermograms of energetic compounds (Figure 19). When describing thermograms of

**Figure 19:** DSC thermogram of the thermal decomposition of aminoguanidinium nitroformate. (Reproduced and modified from [193].)

other energetic compounds, we have attempted to always include information about the heating rate at which the data were obtained.

## 12.5 Other Aminoguanidinium Salts

Based on TG-DTA-MS measurements, aminoguanidinium 5,5'-azobis-1*H*-tetrazolate melted at 482 K, followed immediately by a rapid exothermic decomposition, leading to 50% weight loss [237]. The decomposition started with cleavage of the heterocyclic ring, which produced nitrogen and cyanamide with generation of heat.

Mono-, di-, and triaminoguanidinium sulfate and azidoformamidinium sulfate are not used as rocket propellants, but they are useful intermediates in the synthesis of other nitrogen-rich compounds and their crystal structures were compared to those of salts with other anions [238].

The kinetics of the thermal decomposition of aminoguanidinium 5,5'-azobis-1*H*-tetrazolate (AGAT), which is a promising candidate for gas-generating agents in airbags, were investigated by MS [239]. The main path of decomposition of AGAT was a single elementary process. The activation energies for the main decomposition obtained under helium by non-isothermal analysis and isothermal analysis were 207 and 209 kJ/mol, respectively.

The effects of initial temperature, pressure, particle size, and composition ratio on the burning rate of aminoguanidinium 5,5'-azobis-1*H*-tetrazolate (AGAT)/ammonium nitrate (AN)-based gas generants were studied in a temperature-controlled chimney-type strand burner [240, 241]. More detailed AN/AGAT burning rate data are described in a future set of several volumes on solid propellants and gas generants to be published as part of *Encyclopedia of Rocket Propellants*. The thermal decomposition of AGAT in comparison to that of AN is shown in Figure 20.

The decomposition of AGAT occurs in one sharp exothermic peak, while the endothermic phase changes and decomposition of AN are spread over a wide temperature range. Physical properties of aminoguanidinium 5-aminotetrazolate and several other 5aminotetrazolate-salts are also summarized in the chapter "Heterocyclic Amines" [206].

Aminoguanidinium 1-methyl-5-nitriminotetrazolate can be prepared by reaction of aminoguanidinium bicarbonate with 1-methyl-5-nitriminotetrazole, which is made from 5-aminotetrazole through methylation and nitration [242]. Optimizing the nitration dosage, reaction temperature, and time resulted in a good yield of 81%. The products were characterized by means of <sup>1</sup>H NMR, IR, and MS.

**Figure 20:** DTA curves of AGAT and AN at heating rate of 5 K/min in helium. (Republished and modified from [241], with permission of ©2011 Taylor & Francis, [www.tandfonline.com](http://www.tandfonline.com))

## 13 Diaminoguanidine

Diaminoguanidine,  $C_1H_7N_5$ ; carbonimidic dihydrazide; CAS RN [4364-78-7], is rarely used as an intermediate. When trying to prepare it by reaction of guanidine with hydrazine hydrate, it is difficult to stop the amido group replacement at exactly this intermediate step between aminoguanidine and triaminoguanidine. The reaction of diaminoguanidine with nitrous acid leads to a variety of tetrazole derivatives [125, 127].

### 13.1 Diaminoguanidinium Nitrate

Diaminoguanidinium nitrate, diaminoguanidine nitrate, DAGN; carbonimidic dihydrazide, nitrate (1:1);  $C_1H_8N_6O_3$ , CAS RN [37160-07-9], molecular mass 152.11, nitrogen content 55.25% N, is a good source of nitrogen for gas generants. Diaminoguanidinium nitrate and the corresponding picrate and perchlorate have been patented as explosives [243]. Its melting point is 415–417 K (142–144 °C) and it will explode when rapidly heated to 563 K (290 °C). Its impact sensitivity (50% point) is 40 cm with a 2-kg weight. With an excess of nitric acid, diaminoguanidine may form a dinitrate salt. Chemical Abstracts nomenclature called this salt “Carbonimidic dihydrazide, dinitrate” with a CAS RN [244639-25-6P].

Diaminoguanidinium nitrate melts at 417–418 K (144–145 °C) and the temperature at the maximum of the exotherm in the DTA is 533 K (260 °C), where it decomposes in

a violent reaction [172]. In a vacuum stability test at 393 K (120 °C) for 40 h comparing GuN, DAGN, and TAGN, DAGN was the least stable with a gas evolution of 1.92 versus 0.23 cm<sup>3</sup> for GuN and 1.06 cm<sup>3</sup> for TAGN [244]. The IR spectrum of diaminoguanidinium nitrate is shown in Figure 21.

**Figure 21:** IR spectrum of diaminoguanidinium(1+) nitrate. (Reproduced and modified from [125], with permission from Levering Estate.)

### 13.1.1 Toxicity of Diaminoguanidinium Nitrate

Diaminoguanidinium nitrate (DAGN) was among 13 other chemicals tested as ingredients for “non-toxic” propellants [245]. The results in hepatocytes showed a dose-dependent decrease in mitochondrial activity (MTT), an increase in lactate dehydrogenase (LDH) leakage, and depletion of glutathione (GSH) levels. Responses to hydrazine were used as reference values for ranking the other chemicals. According to the MTT assay, the hydrazine-containing compounds were the most toxic, but DAGN was at the lower end of that list where the salts were listed in the order hydrazinium nitrate (HN) diethylhydrazinium nitrate (DEHN) 1,4-dihydrazinotetrazinium nitrate (DHTN) methylhydrazinium nitrate (MMHN) 2-hydroxyethylhydrazinium nitrate (HEHN) DAGN nitroaminoguanidinium nitrate (NAGN).

### 13.2 Other Diaminoguanidinium Salts

Hypergolic liquid bipropellant fuels that are self-igniting with N<sub>2</sub>O<sub>4</sub> as the oxidizer can be made from guanidinium or mono-, di-, and triaminoguanidinium as the cation and

dicyanamidate or tricyanomethanide as the anion [246]. Properties of these salts are summarized in Table 23. See also [238].

**Table 23:** Properties of hydrazidinium dicyanamidates and tricyanomethanides.

| Compound name                        | Formula                                      | Melting point |                 | Decomposition onset |     | Density<br>g/cm <sup>3</sup> |

Data source: [246]

Diaminoguanidinium azide, [(H<sub>2</sub>NNH)<sub>2</sub>C=NH<sub>2</sub>]<sub>3</sub>N<sub>3</sub>, C<sub>1</sub>H<sub>8</sub>N<sub>8</sub>, with a molecular mass of 132.13 g/mol (7.568 mol/kg) and a density of 0.0513 lb/in<sup>3</sup> = 1.43 g/cm<sup>3</sup> has an enthalpy of formation of +741 cal/g = +97.908 kcal/mol = +409.6 kJ/mol [124]. It contains 84.8% nitrogen and is a good source of nitrogen for gas generators.

The diaminoguanidinium salt of 3-nitro-1,2,4-triazol-5-one, CH<sub>8</sub>N<sub>5</sub><sup>+</sup>•C<sub>2</sub>H<sub>1</sub>N<sub>4</sub>O<sub>3</sub><sup>−</sup>, molecular mass 219.16 g/mol, crystallized in triclinic crystals, space group *P* $\bar{1}$ , with the cell parameters of *a* = 6.735(2) Å, *b* = 6.753(2) Å, *c* = 9.844(2) Å,  $\alpha$  = 88.29(2)°,  $\beta$  = 77.17(2)°,  $\gamma$  = 86.50(2)°, *V* = 435.7 Å<sup>3</sup>, *Z* = 2, and  $\rho$  = 1.671 g/cm<sup>3</sup> [247].

## 14 Triaminoguanidine

The correct nomenclature name for triaminoguanidine, CH<sub>8</sub>N<sub>6</sub>, would be 1,2,3-triaminoguanidine, with the numbers indicating the nitrogen atoms to which the additional amino group has been attached.

Chemical Abstracts Service (CAS) nomenclature may also call triaminoguanidine by the unusual names carbonohydrazone dihydrazide or carbonohydrazonic dihydrazide.

Triaminoguanidine, TAG, CH<sub>8</sub>N<sub>6</sub>, CAS RN [2203-24-9], *M* = 104.12 g/mol, contains 80.7% nitrogen. Triaminoguanidine can be prepared by reaction of dicyandiamide with hydrazine hydrate. Triaminoguanidine free base exists in the form of colorless crystals that melt at 385–393 K (112–120 °C).

The reaction between hydrazine hydrate and carbon tetrachloride at reflux can form triaminoguanidinium chloride that can be converted to the free base or other TAG salts.

Free TAG base is not very stable. It can be prepared by passing a TAGN solution through a cation-exchange column. Once a solution of the free base is at hand, it can be neutralized with any of the oxygen-rich or energetic anion acids to obtain energetic high-nitrogen compounds, salts of the triaminoguanidinium ion. The free base can be used to synthesize a number of high-nitrogen compounds and all TAG salts, such as triaminoguanidinium 5-aminotetrazolate with 81.4 mass-% nitrogen. With strong nitric acid, triaminoguanidine can also form triaminoguanidinium(2+) dinitrate salts [74].

The structure of the free base was investigated in an effort to better understand the molecular structure of its salts [248–250]. 1,2,3-Triaminoguanidine free base crystals are monoclinic, space group  $P2_1/c$ , with the lattice parameters  $a = 7.460(3)$ ,  $b = 10.274(2)$ ,  $c = 6.343(3)$  Å,  $\beta = 110.8^\circ$ ,  $V = 454.5$  Å<sup>3</sup>,  $Z = 4$ ,  $\rho = 1.52$  g/cm<sup>3</sup>.

The enthalpies of formation of triaminoguanidine free base vapor and other guanidine derivatives were calculated by quantum mechanical methods [111].

In 14 hydrazides, <sup>14</sup>N nuclear quadrupole resonance studies were performed at 77 K [251]. The results indicated extensive delocalization of the charge in the  $\pi$ -orbital of the substituted nitrogen atom. The charge lost to the acyl oxygen is of the order of 0.3 electrons. This loss of  $\pi$ -electrons is partially balanced by an increased polarization of the  $\sigma$ -bonds. In symmetrical hydrazides this amounts to an excess charge density in the order of 0.1 electrons. In hydrazides retaining an  $-\text{NH}_2$  group, the charge in the N–N bond is polarized towards the substituted nitrogen atom.

An excellent summary with 53 references on triaminoguanidinium compounds including information on molecular structure, preparation, physicochemical properties, explosion characteristics, and applications was published in 2008 [252] but could not be translated in time to be included in this book.

### 14.1 Triaminoguanidinium Nitrate

Triaminoguanidinium nitrate, also known as 1,2,3-triaminoguanidinium nitrate, TAGN,  $[(\text{H}_2\text{NNH})_3\text{C}^+]\text{NO}_3^-$ ,  $\text{CH}_9\text{N}_7\text{O}_3$ , triaminoguanidine nitrate; CAS RN [4000-16-2], is a valuable propellant and gas generant ingredient. It has a very high nitrogen content (58.67 mass-% N) and is relatively stable. It has been used in gas generants for airbag inflators, as a coolant in gun propellants to reduce barrel wear and muzzle flash, and in many other propellant formulations. With an excess of nitric acid, TAG may also form a dinitrate. Chemical Abstracts nomenclature called this compound “Carbonohydrazonic dihydrazide, dinitrate” with a CAS RN [60612-44-4P].

### 14.1.1 Preparation of Triaminoguanidinium Nitrate

Triaminoguanidinium nitrate can be prepared by reaction of hydrazinium(1+) nitrate with calcium cyanamide or dicyandiamide in presence of hydrazine hydrate. The other method starts with guanidinium nitrate, where gradual substitution of amino groups by hydrazino groups is possible by treating guanidinium nitrate with anhydrous hydrazine, and removal of the ammonia formed in the equilibrium.

Initially, if guanidinium nitrate is dissolved in hydrazine without chemical reaction, a low-freezing, short-lived eutectic is observed at 30% guanidinium nitrate that freezes at 246 K (−27 °C) [253]. Then, within a few hours, a reaction takes place in which ammonia is liberated and an insoluble salt is formed that precipitates at room temperature. Reaction of hydrazine with guanidinium salts leads to progressive replacement of amino groups and the imino group by hydrazino groups:

It would be difficult to stop this reaction at exactly the mono- or disubstituted stage. On the other hand, an excess of hydrazine should be avoided because it will destabilize the TAGN product. Many of the guanidine–hydrazine reactions result in undesirable by-products as the result of ring-closure reactions. Aminoguanidine may close a ring to form guanazole:

Diaminoguanidine may close a ring structure to form guanazidine:

The formation of colored impurities in TAGN has been blamed for irregular ballistic behavior and incompatibility problems of propellants formulated with this material. Other unwanted ring-closure reactions may lead to pyrazoline derivatives [254].

The sample purity affects the storability of TAGN even before it is processed into propellants [255]. Storage of recrystallized TAGN in IPA resulted in impurity formation.

One of the most easily obtained triaminoguanidinium compounds is triaminoguanidinium nitrate (TAGN) produced by reaction of guanidinium nitrate and hydrazine [256, 257] or hydrazine hydrate with an additional nitrate ion (from ammonium nitrate) as reaction catalysts [258]. Additional nitrate can be added to the starting mixture in the form of hydrazinium nitrate or ammonium nitrate [259] or some dilute nitric acid [260] to improve the yield. For instance, a solution of 74.5 parts by mass GuN in 400 parts by mass of 37.5% hydrazine in water and 12 parts by mass of AN was heated for 1 h at 355–275 K (82–102 °C) to expel the ammonia formed by the reaction. The TAGN crystallized in 68% yield on cooling to 283 K (10 °C). Doubling the amount of AN increased the TAGN yield to 75%; quadrupling the amount of AN increased the TAGN yield further to 83%.

Reacting a suspension of guanidinium nitrate in a C<sub>1</sub> to C<sub>5</sub> alcohol with 64% hydrazine in boiling alcohol gave TAGN in 94% yield with a minimum of melamine contamination [261]. A similar patent describes the synthesis of triaminoguanidinium salts by reacting guanidinium salts or cyanamide with hydrazine and/or hydrazine salts in an aliphatic C<sub>3</sub> to C<sub>5</sub> alcohol [262].

There are no color changes or other specific IR or UV absorption spectra that could be used to monitor the progressive replacement of one, two, and three amino groups by hydrazine and derive kinetics for the multi-step reaction. Instead, the kinetics of the guanidinium nitrate–hydrazine hydrate reaction were examined using the off-gas ammonia in a batch reactor at 366 K [263]. There are two reactions contributing ammonia to the off-gas, one the desirable TAGN-producing reaction and the other the metathetical reaction of AN with hydrazine. By measuring the ammonia formation rate of the AN–hydrazine reaction separately, the guanidinium nitrate–hydrazine reaction rate can be derived by the difference. The kinetics of the two reactions are different, so that the global rates measured by ammonia evolution can be used for sizing a continuous-flow stirred tank reactor, which would be more economical to operate than a batch process. Instead of obtaining coarse and irregular shaped crystals, it would be better to adjust process parameters so that the product is microcrystalline TAGN [264].

Another process for making TAGN starts out with cyanamide and reacts it with hydrazinium nitrate in aqueous solution

In one example, 4.2 g cyanamide, 9.5 g HN, 12.5 g 80% hydrazine hydrate, and 30 mL water were heated in a water bath for 4 h [265]. The TAGN crystals precipitated on cooling, were filtered, washed with methanol, and dried to give 14 g of TAGN in 83.7% yield. The salt melted at 479 K (206 °C) with decomposition. The low melting point indicates that the product may not have been very pure. The melting point should be at least 489 K (216 °C).

Instead of starting with cyanamide or calcium cyanamide, TAGN can be prepared from dicyandiamide, hydrazinium nitrate, and hydrazine hydrate [266]:

A typical reaction mixture was made up of 0.2 mol dicyandiamide, 0.25 mol hydrazinium nitrate, and 0.6 mol hydrazine hydrate. The TAGN yield was 87.7% and the melting point of the product was 215–216 °C. A similar method was used to make tris(dimethylamino)guanidinium nitrate by reaction of 0.2 mol dicyandiamide, 0.25 mol UDMH nitrate, and 0.6 mol UDMH.

Another method for preparation of TAG or TAGN starts with calcium cyanamide, a compound that was once used as a fertilizer and is readily available in industrial quantities. In order to prepare TAGN or TAG, a  $\text{CaCN}_2$  aqueous solution was treated at 363–403 K (90–130 °C) with a < 225% excess of a hydrazinium(I) nitrate solution [267]. The reaction mixture was treated with carbonates to precipitate  $\text{CaCO}_3$ , giving TAGN in at least 95% yield, along with 90% of the unreacted  $\text{N}_2\text{H}_4$ . Thus,  $\text{CaCN}_2$  of 68.94% purity was added to a 90% aqueous solution of hydrazinium(I) nitrate at 383 K (110 °C), stirred for 2.5 h,  $\text{H}_2\text{O}$  added, the temperature adjusted to 358 K (85 °C),  $(\text{NH}_4)_2\text{CO}_3 \cdot \text{H}_2\text{O}$  slowly added, filtered, the filtrate and washings cooled, and the precipitated TAGN removed to give a 94.8% yield. TAGN can be treated with an alkali and DMF is added to precipitate the free base TAG. In order to prepare the free base, a solution of 5 g TAGN and 1.2 g NaOH in 20 mL  $\text{H}_2\text{O}$  was treated with 40 mL DMF, chilled overnight, and the precipitate of TAG obtained in 66.5% yield. The base can be identified as its picrate which melts at 443–444 K (170–171 °C).

The use of a molar excess of hydrazine nitrate reactant relative to the amount of cyanamide reactant employed insures that all of the TAG will be neutralized to the nitrate salt rather than the more unstable TAG base, which is subject to decomposition to form undesirable by-products [268].

After a comparison of several candidate chemical synthesis methods for TAGN, such as the dicyandiamide method, calcium cyanamide method, cyanamide method, and the guanidinium nitrate method, the guanidinium nitrate method was selected for optimization, improvement, and scale-up [269]. The technology of TAGN synthesis by a one-step process from guanidinium nitrate using low-concentration hydrazine hydrate as raw material was scaled up to the kilogram scale. The yield was 94.8% and product purity based on characterization by melting point measurement, elemental analysis, IR, and XRD was very good.

#### 14.1.1.1 Identification and Removal of TAGN Contaminants

The problem associated with impurities in TAGN did not receive wide attention until a large shipment of TAGN desensitized with isopropanol (IPA) was delivered to Eglin AFB, Florida, from Rocketdyne in 1978 and stored for several years. Previously, TAGN was generally handled as a dry material or, if wet with a diluent, was used within

a few days. Examination of some of the TAGN shipment revealed that the IPA diluent exhibited various shades of yellow, brown, and pink.

Contaminants in TAGN can result in product discoloration and burning rate irregularities of propellants prepared with the discolored compound. It was therefore important to identify the source of discoloration and develop methods to avoid contamination during production and storage [270]. It was suggested that the culprit for discoloration is a small amount of the free base, triaminoguanidine, in the product. Triaminoguanidine is sensitive to oxygen in air and will form a variety of autoxidation products, including azo dyes and heterocyclic ring compounds. Trace metal cations will catalyze this oxidation reaction and subsequent ring-closure reactions. It is recommended to prepare and recrystallize TAGN only in non-metallic process vessels under an inert atmosphere and maintain slightly acidic conditions. Pink crystals can be washed with deionized water and the pink color removed. Other wash fluids tested were acetone-free IPA, IPA/hexane mixtures, and *n*-hexane. TAGN crystals appear as hollow cylinders when viewed under a microscope. It was believed that much of the pink color was due to liquid trapped in the hollow spaces of the cylinders. Discoloration was more likely to occur in polar fluids. TAGN wet with IPA also had a tendency to agglomerate (due to marginal solubility in IPA). TAGN processed in Freon-113 did not agglomerate, but had other ballistic irregularity problems, showing the worst irregularities of all solvents tested. Even doubly recrystallized TAGN again formed impurities after storage in IPA. TAGN should not be stored in IPA or any diluent in which TAGN has some solubility because of impurity formation. Impurities in solution can generally be removed by washing with IPA and presumably also with other polar solvents. Physically entrapped impurities can be removed by once again washing the TAGN after grinding it. The optimal conditions for synthesis of TAGN while avoiding colored impurities is to use an aqueous medium kept free of metal ions, in minimally alkaline conditions, with an absence of atmospheric oxygen.

As with most solid propellant oxidizers and additives, it is important not only to produce a pure ingredient, but also to produce it in the correct and reproducible particle size. In the case of TAGN (and many similar additives), it is possible to comminute a coarse product by wet-milling a suspension in an inert fluid [271]. In one example, 2 h of wet-milling of 3 kg coarse (av. 150  $\mu\text{m}$ ) TAGN in 20 L of 1,1,1-trichloroethane resulted in TAGN with an average particle size of 15  $\mu\text{m}$ , similar to that obtained with a colloid mill.

#### 14.1.2 Physical Properties of Triaminoguanidinium Nitrate

The molecular mass of TAGN,  $\text{CH}_8\text{N}_7\text{O}_3$ , is 166.12 g/mol = 6.020 mol/kg. The melting point of TAGN is 489 K = 216 °C = 420 °F (decomposition). The density of TAGN crystals is  $\rho = 1.594 \text{ g/cm}^3$  [272]. The oxygen balance of TAGN is -33.5% for combustion to  $\text{CO}_2$ . See also [273]. TAGN is not very soluble in water (Table 24).

**Table 24:** Solubility of triaminoguanidinium nitrate in water.

| Temperature |     | Solubility       |
|-------------|-----|------------------|
| K           | °C  | g/100 g solution |
| 273         | 0   | 1.34             |
| 293         | 20  | 3.4              |
| 313         | 40  | 7.5              |
| 333         | 60  | 16.3             |
| 353         | 80  | 30               |
| 373         | 100 | 50               |

Data source: [274]

**Infrared Spectra of TAGN.**

The IR spectra of TAGN are important for quality control and to study intermediates in the synthesis or thermal decomposition of this substance. In particular, it is of interest to observe the changes occurring in the spectra of guanidinium nitrate upon progressive substitution of amino groups by hydrazino groups (Figure 22).

**Figure 22:** Infrared spectra of the tri-, di-, monoamino and unsubstituted guanidinium nitrates. (Reproduced and modified from [275].)

Upon gradual and stepwise removal of the NH groups from TAGN, the bands due to N—H asymmetric stretch begin to broaden. The N—N band of medium intensity at  $1129\text{ cm}^{-1}$  in the TAGN spectrum has a significantly lower relative intensity in DAGN at  $1127\text{ cm}^{-1}$  and is barely discernable in MAGN at  $1120\text{ cm}^{-1}$ . The N—N band is fairly weak, even in TAGN which has three N—N bonds. DAGN has one N—N bond fewer and the band is weaker than in TAGN. In MAGN (AGN; only one N—N bond) the band is barely discernible. The other prominent bands in TAGN spectra are the nitrate bands, the strongest of which is at  $1384\text{ cm}^{-1}$ , and a small but sharp band at  $825\text{ cm}^{-1}$  (Figures 23 and 24). These  $\text{NO}_3^-$  bands can be identified by comparison to a pure sample of  $\text{KNO}_3$ . The infrared spectra and band assignments for TAGN have been reported previously

**Figure 23:** Infrared spectrum of triaminoguanidinium nitrate. (Reproduced and modified from [21].)

**Figure 24:** IR spectrum of triaminoguanidinium nitrate. (Reproduced and modified from [125], with permission from Levering Estate.)

[276]. The IR-active internal modes of polycrystalline TAGN below room temperature were unaffected by the transitions at 258 and 270 K, indicating that the relative atomic movements must be small. At 400 and 420 K, IR spectral changes with activation energy of 6.7 kJ/mol (1.6 kcal/mol) at 406 K occurred in the NO<sub>3</sub> sublattice. IR, XRD, and XPS spectra of TAGN are shown in [277].

#### 14.1.2.1 Thermodynamic Properties of Triaminoguanidinium Nitrate

The heat capacity of TAGN is listed in Table 25 and enthalpy data are listed in Table 26.

**Table 25:** Heat capacity of triaminoguanidinium nitrate.

| Temperature |    | Heat capacity                        |                                   |
|-------------|----|--------------------------------------|-----------------------------------|
| K           | °C | cal g <sup>-1</sup> °C <sup>-1</sup> | J g <sup>-1</sup> K <sup>-1</sup> |
| 293         | 20 | 0.391                                | 1.634                             |
| 303         | 30 | 0.403                                | 1.688                             |

TAGN Formula weight: 166.12 g/mol; TAG Formula weight: 104.12

For a comparison of the heats of combustion, enthalpies of formation, and enthalpies of solution of guanidinium nitrate with those of mono- and triaminoguanidinium nitrate, see Table 10.

### 14.1.2.2 Molecular Structure of Triaminoguanidinium Nitrate

Similar to the guanidinium ion, the triaminoguanidinium is also stabilized by the symmetry and multiplicity of resonance structures that can be written for the protonized compound. It should be pointed out that the positive charge on the TAG cation or on the guanidinium ion cannot be exactly located: one can write structures in which the proton attaches itself to any of the three hydrazino groups. The positive charge can also reside on the carbon, forming a symmetrical carbonium ion, the symmetry of which allows multiple resonance structures to which the thermal stability of this compound can be accredited.

Triaminoguanidinium nitrate (TAGN) is a frequently tested high-nitrogen compound and one of the thermally most stable organic hydrazine derivatives. The thermal stability can be explained by the highly symmetrical structure and resonance stabilization of the cation. The  $CN_6$  skeleton of the ion is planar. The ion is planar with the exception of the three pairs of terminal amino hydrogen atoms. The C—N bonds have partial double bond character. Hydrogen bonding between  $TAG^+$  cations and nitrate anions strengthens the stability of the crystals. The rotation of the nitrate ion (also a planar ion) is hindered by the forces of hydrogen bonding in a  $TAG^+$  environment. TAGN undergoes a phase change around 263 K. TAGN crystals occur in a low-temperature modification with a different crystal structure [283].

TAGN at room temperature crystallizes in orthorhombic crystals. Based on X-ray diffraction, the crystal structure is  $Pbcm$ ,  $a = 8.389(7)$ ,  $b = 12.684(8)$ ,  $c = 6.543(5)$  Å,  $z = 4$ ,  $\rho_{\text{measured}} = 1.60 \text{ g/cm}^3$ , X-ray density =  $1.594 \text{ g/cm}^3$  [284]. The crystal structure consists of layers of ions parallel to (001). Each nitrate ion is hydrogen bonded to two cations within each layer, and also to two cations in alternate layers. The structure consists of layers of planar triaminoguanidinium cations and nitrate anions located on mirror planes at  $\pm 1/4c$ . The cations are coplanar with the mirror planes (except for the amino H atoms), while each anion is bisected by the mirror plane with only the central N atom and one O atom on the mirror.

Neutron diffraction gave similar results [285]: orthorhombic crystals,  $Pbcm$ ,  $a = 8.389$ ,  $b = 12.684$ ,  $c = 6.543$  Å,  $Z = 4$ ,  $\rho_m = 1.60 \text{ g/cm}^3$ ,  $\rho$  (neutron diffraction) =  $1.594 \text{ g/cm}^3$ . According to the neutron diffraction results, the structure is made up of an infinite three-dimensional network of N—H...O hydrogen bonds linking the 1,2,3-triaminoguanidinium ions to the nitrate ions. The librational motions of the nitrate ion have a particularly large amplitude about an axis which is close

to the perpendicular to the plane of the ion. The differences between the atomic coordinates reported by Choi and Prince [285] and those reported by Bracuti [284] are closely correlated with the amount of thermal motion. Atoms near the centers of molecular groups agree within twice the estimated standard deviation, but atoms on the peripheries of the groups and all hydrogen atoms differ by four to five times the standard deviation. Neutron radiography is more accurate in locating hydrogen atom positions; therefore, the neutron hydrogen atom parameters should be more accurate.

The crystal and molecular structures of triaminoguanidinium nitrate were determined using single-crystal XRD to see if its unique burning rate behavior is structure related [272]. The TAGN structure consists of layers of ions parallel to the (001) plane, held together by van der Waals' forces and hydrogen bonding.

In trying to elucidate the TAGN structure by way of both experimental and theoretical study, MINDO/3 semi-empirical SCF-MO calculations of the triaminoguanidinium ion have provided information on the total energy, core-core repulsion energy, electronic energy, charge distribution, heat of formation, ionization potential, and dipole moment of the cation [286, 287]. The effect of rotation across the N–N bonds on the values of these parameters was studied. The configuration of the cation with the lowest total energy corresponds to the configuration determined by X-ray analysis on a crystal of TAGN. The energy barrier for the rotation of the three primary amino groups is of the order of 1.38 eV (133 kJ = 31.8 kcal).

In order to fully characterize nitrate ion motion/disorder in TAGN, the molecular structure of TAGN was redetermined on the basis of a positionally disordered nitrate ion model and compared with results from a model that assumed dynamic rigid-body motion in the nitrate ion [288]. It was concluded that at room temperature, the nitrate ion undergoes rigid-body motion.

A rigid-body motion study of TAGN was originally initiated to determine whether nitrate ion libration might be responsible for the fast burning rate of TAGN. A low-temperature polymorph of TAGN was discovered during the course of this rigid-body motion study [278, 283, 289, 290]. A single-crystal XRD structure determination of the low-temperature form was undertaken. The crystal structure was determined including space group, lattice parameters, atomic coordinates, extent of hydrogen bonding, and XRD density. At 169 K (–104 °C), TAGN exists in the orthorhombic space group *Pbca*, with  $a = 33.058$ ,  $b = 12.573$ , and  $c = 6.573$  Å. At 263 (–10 °C), TAGN transforms into the orthorhombic space group *Pbcm*, with unit cell dimensions at 296 K of  $a = 8.366$ ,  $b = 12.649$ , and  $c = 6.556$  Å. The density of the low-temperature form is 1.63 g/cm<sup>3</sup> and the density of the room-temperature form is 1.60 g/cm<sup>3</sup>. The densities of the two polymorphic forms of TAGN are very similar, such that phase changes should not cause grain delamination and grain swelling as observed with AN-based propellants. At room temperature, the crystal structure consists of layers of TAG cations and nitrate anions positioned in mirror planes normal to the *c*-axis. At 169 K (–104 °C), TAGN still

exists as a layered structure, but now the quasi-planes of the TAG cations are no longer coplanar with the layers and the nitrate ions are not normal to the layers.

The structure of TAGN and a similar TAG azide have been studied in an effort to explain the thermal stability behavior of these compounds.

### 14.1.3 Chemical Properties of Triaminoguanidinium Nitrate

#### 14.1.3.1 Analysis of TAGN

Polarographic determination of TAGN in a phosphate ion-buffered solution at pH 9 or in neutral or weakly acidic solutions revealed two peaks: the first is specific for TAGN and the second is observed with similar compounds (MAGN and DAGN) [291]. The first peak had characteristics for a catalyzed reaction, the second peak appeared to be diffusion controlled. The best medium for this analysis was a phosphate-buffered medium at pH 9.0 or a neutral or slightly alkaline medium with  $(\text{CH}_3)_4\text{N}^+\text{Br}^-$  as the supporting electrolyte. Both media exhibited good stability over time. This method can be used to determine TAGN content in propellant mixes or for quality control during TAGN production.

Ion chromatography can be used to monitor the progress of the stepwise replacement of amino groups with hydrazino groups in the reaction of guanidinium nitrate with hydrazine [292]. A direct, quantitative, chromatographic method has been developed for determination of AGN, DAGN, and TAGN as well as hydrazine in the reaction mixture. The ion chromatographic method has been used to monitor the synthesis of TAGN and to optimize reaction conditions.

#### 14.1.3.2 Thermal Stability of Triaminoguanidinium Nitrate

Triaminoguanidinium nitrate is one of the more stable high-nitrogen compounds, which is why it has been extensively investigated as a constituent in gun propellants and gas generants.

#### Rapid Pyrolysis

High-rate thermolysis of TAGN with simultaneous identification of the off-gassing products by FTIR has shown that the initial (first stage) decomposition products were ammonia  $\text{NH}_3$  and nitric acid  $\text{HNO}_3$  [276].  $\text{HNO}_3(\text{G})$  disappeared within 0.2s. The second stage of decomposition at higher temperatures produced  $\text{NO}_2$ ,  $\text{N}_2\text{O}$ , and  $\text{HCN}$ , followed by third-stage decomposition products of  $\text{CO}_2$ ,  $\text{H}_2\text{O}$ ,  $\text{NO}$ , and possibly  $\text{NO}_2$ . If the sample cell is pressurized to above 448 kPa (65 psia) with argon gas, a crossover takes place from decomposition products (dominance of nitrogen oxides) to those mostly characteristic of deflagration (dominance of carbon oxides). The thermolysis product distribution from TAGN pyrolysis was then compared to that from  $[\text{C}(\text{CH}_2\text{NH}_3)_4](\text{NO}_3)_4$ ,  $[\text{NH}_3\text{OH}]\text{NO}_3$  and  $\text{NH}_4\text{NO}_3$ .

### Differential Scanning Calorimetry Results

In the DSC at 10 °C/min, exothermic decomposition of TAGN began immediately after the melting point and reached its maximum at about 505 K = 232 °C [275] (Figure 25). A second, slightly sharper exotherm was observed at 551 K = 278 °C, with a smaller and more variable exotherm (538 K = 265 °C) occurring between the two larger exotherms. The first exotherm (just after the melting point) was the one associated with the reactions studied in the mass spectrometer (see next paragraph; mainly N<sub>2</sub> and NH<sub>3</sub> evolution). This was evidenced by the fact that when the residue from the MS experiments was run in the DSC, the first exotherm normally seen in TAGN was no longer observed.

The thermal decomposition of TAGN involved three stages with different rates of heat generation and mass loss. The first stage corresponded to an exothermic rapid reaction between 0 and 27% mass loss at up to 498 K = 225 °C, the second stage corresponded to a relatively slow endothermic reaction between 27 and 92% mass loss

**Figure 25:** Thermogram of TAGN decomposition in a DSC at 10 °C/min. (Reproduced and modified from [275].)

at up to 573 K = 300 °C, and the third stage was a very slow endothermic reaction between 92 and 100% mass loss, going to completion at 623 K [293]. The endotherm during the second stage was a melting-phase change process. The exothermic rapid reaction observed at the early stage of the decomposition occurred immediately after the endothermic phase change from solid to liquid. Since the weakest chemical bond in the TAGN molecule is the N–N bond (159 kJ/mol), the initial bond breakage should be in the hydrazino groups and three NH<sub>2</sub> radicals split off [294, 295]. The energy released by the dissociation of the NH<sub>2</sub> radicals (104.3 kJ/mol = 24.93 kcal/mol) is the heat produced at the early-stage decomposition of TAGN. The burning rate of TAGN is dominated by the release of the NH<sub>2</sub> radicals. It should be noted that the burning rate of TAGN is almost twice that of HMX, even though the energy contained in the unit mass of TAGN is less than that of HMX. The HNO<sub>3</sub> attached to the TAG cation is not the fragment to produce the exothermic rapid reaction observed at the early-stage decomposition process.

According to DSC analysis results, TAGN melts at 489–493 K (216–220 °C; the endothermic effect of 33.5–50.2 kJ/kg or 8–12 kcal/g) and decomposes in two stages (two exotherms with maxima at approximately 503 and 543 K = 230 and 270 °C). The heat release in the first stage (the first exotherm) is higher than in the second, and is equal to 837–1255 kJ/kg (200–300 kcal/g). Based on DTA and TGA analysis, it was shown that the fast exothermic reaction proceeded with the loss from 27 to 55% of mass [296]. In the second stage of decomposition, practically all substance (98%) was gasified (Table 27; Figure 26).

**Table 27:** DSC and DTA/TGA results with TAGN.

| DSC                  | Temperature, °C | DTA/TGA                  | Temperature, °C | Effect                           |

Data source: [296]

**Figure 26:** DTA, TGA, and DSC thermograms of TAGN. (Reproduced and modified from [296].)

The exothermic reaction occurred immediately after the endothermic phase change from solid into liquid. The TGA curve consisted of two steps: The first step corresponded to a rapid reaction also observed in the DTA curve starting at a weight loss of 0% (499 K = 226 °C) and ending at a weight loss of ~55% (511 K = 238 °C). The second stage is a slow weight loss from ~55 to 96% at 623 K (350 °C). The measured DTA values were in good agreement with the literature values [294].

The kinetics of thermal decomposition of TAGN were studied by gas release under isothermal conditions in glass vessels with a Bourdon pressure gauge [297, 298]. The gaseous decomposition products that were not condensed after cooling to room temperature were analyzed chromatographically. The decomposition of crystalline powdered TAGN developed with drastic self-acceleration. The main cause of the acceleration is the progressive melting of the solid during its thermal decomposition. The cor-

responding activation energy is  $\sim 167 \text{ kJ/mol} = 40 \text{ kcal/mol}$ . The rate constant in the range 433–473 K (160–200 °C) can be expressed by the Arrhenius equation

$$\log k = 14.67 - \frac{E_a}{RT}$$

where  $k$  is the reaction constant in  $\text{s}^{-1}$  and  $E_a$  is the activation energy  $E_a = 173000 \text{ J/mol}$ . The decomposition of TAGN in melt solution (a low-melting mixture of TAGN and AN) was 30 times faster than that in the solid state and proceeded at a rate decreasing with time. The main gaseous products of TAGN decomposition under those conditions were  $\text{N}_2$ ,  $\text{N}_2\text{O}$ , and  $\text{H}_2\text{O}$  (but see section entitled “Analysis of Evolved Gases” below). While Lure and Smirnov [297, 298] reported the constants of TAGN thermal decomposition similar to those of AN, HAN, or HN in melt, Serushkin [282] measured that the rate of TAGN thermal decomposition was almost of three orders of magnitude higher than that of AN under the same conditions. See also [299].

The kinetics and mechanism of thermal decomposition of diaminoguanidinium nitrate (DAGN) and triaminoguanidinium nitrate (TAGN) have been studied using TGA, DTA, IR spectroscopy, and hot-stage microscopy [300]. The kinetics of thermolysis have been followed by isothermal TGA and IR. The activation energy,  $E_a$ , for the initial stage of thermolysis of DAGN was  $130 \text{ kJ/mol}$  and  $\log A = 11.4$ . The initial stage of thermolysis of TAGN was analyzed by isothermal TGA and the kinetic parameters were  $E_a = 160.0 \text{ kJ/mol}$  and  $\log A = 16.0$ . Spectroscopic and other results indicated a deamination reaction involving rupture of the N–N bond as the primary step in thermal decomposition.

The kinetics of TAGN thermal decomposition were studied by gas evolution under isothermal conditions in glass manometers in both the solid and the liquid state in a solution of AN or aromatic nitro compounds [301]. The decomposition of solid TAGN is self-accelerating. The main cause of the acceleration is progressive melting of the solid substance during its chemical transformation. TAGN decomposition rates in solution were 10–30 times higher than in the solid state. The main gaseous products of decomposition were  $\text{N}_2$ ,  $\text{N}_2\text{O}$ , and  $\text{H}_2\text{O}$ , giving three mols of gas per mol of TAGN. Nitrous oxide appeared only at later stages of the process. The decomposition of TAGN is different from that of nitrate salts of other nitrogen bases like AN, HN, or HAN. Decomposition of the solid substance was investigated at 433–473 K (160–200 °C) at a loading density of the vessel by the substance ( $m/v$ ; ratio of weight to free volume of vessel) of  $0.04 \text{ g/cm}^3$ . Decomposition of TAGN in the liquid state in solution in molten AN was 30 times faster than in the crystalline state.

The TGA weight-loss curve of TAGN (Figure 27) consisted of a three-stage weight-loss process: the first stage corresponded to the rapid exothermic reaction observed in the DTA curve between 488 and 498 K (215 and 225 °C), corresponding to 27% weight loss [204]. The second stage corresponded to the slow endothermic reaction between 498 and 573 K (225 and 300 °C), corresponding to 65% weight loss. The third stage corresponded to the very slow endothermic reaction beyond 573 K (300 °C), with the

**Figure 27:** Combined TGA-DTA thermogram of TAGN. (Republished and modified from [204], with permission of ©2009 American Institute of Aeronautics Astronautics; permission conveyed through Copyright Clearance Center Inc.)

weight loss of 8% taking place at higher temperature ( $623\text{ K} = 350^\circ\text{C}$ ). The endothermic peak at  $488\text{ K}$  ( $215^\circ\text{C}$ ) in the DTA curve was recognized to be caused by melting.

### Analysis of Evolved Gases.

The gases evolved while heating TAGN in a hot bath from  $423$  to  $493\text{ K}$  ( $150$  to  $220^\circ\text{C}$ ) at a rate of approximately  $10^\circ\text{C}/\text{min}$  were analyzed by MS [275]. The results for TAGN over the temperature range  $463$ – $493\text{ K}$  ( $190$ – $220^\circ\text{C}$ ) were rather similar, with ammonia ( $35$ – $45\%$ ) and nitrogen ( $50$ – $65\%$ ) as the main gaseous products. Other gases found in small amounts included CO ( $2\%$ ), formaldehyde ( $4\%$ ), NO ( $1\%$ ), and possibly hydrazine ( $2\%$ ).  $\text{N}_2\text{O}$  was found in small amounts ( $1\%$ ), usually only at the higher temperatures ( $483$ – $493\text{ K} = 210$ – $220^\circ\text{C}$ ), or if prolonged ( $30$ – $60\text{ min}$ ) heating periods were used.

The gases evolved during TGA of TAGN, AP/TAGN, and AN/TAGN mixtures were analyzed by IR [277]. The DSC thermograms of bulk TAGN and nano-TAGN prepared by milling were very similar (Figure 28). Particle size does not seem to have a major effect on the thermal stability of TAGN. These thermograms are of a better quality than any of those shown above, because they illustrate the effect of different heating rates. While the heat evolution is resolved into several peaks at low heating rates, it merges into one major peak at high heating rates.

**Figure 28:** DSC thermograms of bulk (left) and nano-TAGN (right). (Republished and modified from [277], with permission from ©2019 American Chemical Society; permission conveyed through RightsLink.)

#### 14.1.3.3 Reactions of Triaminoguanidinium Nitrate

Many of the reactions of TAGN are undesirable and already occur during the preparation of TAGN, resulting in contaminants and by-products. On the other hand, TAGN and TAG are valuable building blocks for heterocyclic compounds because of the ease of heterocyclic ring formation. The easiest reactions to perform are those between TAG or TAG salts and carbonyl compounds, such as acetyl acetone. The reaction between acetyl acetone and TAGN gave 1,3,6-bis-(3,5-bismethyl-pyrazole-*N*-yl)-1,2-dihydro-s-tetrazine and 2,α,α'-bis(3,5-bismethyl-pyrazole-*N*-yl)-carbene-acetyl-isopropenyl hydrazine ( $C_{14}H_8Cl_4N_2$ ,  $M = 346.02$ ) [302].

#### 14.1.4 Strand Burning of Triaminoguanidinium Nitrate

This chapter deals only with the strand burning rate of TAGN by itself or perhaps TAGN with burning rate catalysts. TAGN pellets were pressed to achieve a density of  $1.47 \text{ g/cm}^3$ , which is 98% of the theoretical maximum density, and the burning rates were measured in comparison to those of HMX pellets [281, 293]. The results are illustrated in Figure 29. TAGN burns faster than HMX.

The pressure exponent of TAGN is 0.78, which is very similar to that of HMX. The burning rate of TAGN is almost twice that of HMX, although the energy content of TAGN is lower than that of HMX and the adiabatic flame temperature of TAGN is much lower (1000 K lower) than that of HMX. The luminous flame of TAGN combustion stands some distance from the solid surface, with a dark zone in between. The luminous flame moves closer to the surface if the pressure is increased.

The combustion behavior and strand burning rates of TAGN were investigated over a wide pressure range and a detailed combustion mechanism has been proposed [282, 303]. Temperature profiles in the TAGN combustion wave were measured with

**Figure 29:** Strand burning rates of TAGN in comparison to HMX. (Republished and modified from [281], with permission of ©2002 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center Inc.)

thin-wire tungsten/rhenium thermocouples. It was proposed that the burning rate of TAGN is governed by processes in the condensed phase. It was shown that the surface temperatures in combustion of TAGN as well as those of other onium salts are controlled by the process of dissociation into the free base and the acid:

A comparison of the most recent strand burning rates of TAGN determined in the form of pressed cylinders of 0.92–0.94 theoretical maximum density ( $1.594 \text{ g/cm}^3$ ) confined in transparent acrylic tubes of 7-mm inner diameter to burning rates determined at other laboratories showed a remarkably good agreement between the different sets of data (Figure 30).

TAGN in the form of samples pressed into 7-mm acrylic tubes can sustain stable burning at atmospheric pressure, although it was obvious that this is the lower pressure limit of TAGN combustion. The burning rate pressure dependence can be divided into three segments with different pressure exponents: in the interval 0.1–2 MPa

$$r_b = 6.11p^{0.88};$$

**Figure 30:** Comparison of TAGN burning rates measured in different laboratories. (Republished and modified from [282], with permission of ©2013 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center, Inc.) 1 – gray circles: Serushkin et al. [282]; 2 – + signs: Kubota, Hirata, and Sakamoto [294]; 3 – x signs: Kubota [304]

in the interval 2–4 MPa

$$r_b = 8.76p^{0.34};$$

and in the interval 4–10 MPa

$$r_b = 5.97p^{0.63}$$

The surface temperature of burning TAGN increased with pressure. The surface temperature of burning TAGN was higher than that of burning AN (Figure 31), which can be explained by the fact that TAG is a stronger base than ammonia and it takes more energy to dissociate it.

It was concluded that the burning rate of TAGN is determined by processes in the condensed phase. The surface temperature in combustion of TAGN, as well as for AN and AP, is controlled by a dissociation process similar to those postulated for other onium salts [305]. It has been shown that the reaction that controls the burning rate of TAGN during combustion is decomposition at the surface temperature. For TAGN

**Figure 31:** Effect of pressure on surface temperatures of burning TAGN and AN. (Republished and modified from [282], with permission of ©2013 John Wiley Sons – Books; permission conveyed through Copyright Clearance Center, Inc.)

in pressure intervals of 0.1–2 MPa, the heat release in the condensed phase provided enough heat to warm up and melt the TAGN, and the heat flux coming from the gas phase to the surface was spent only for evaporation of non-decomposed TAGN and had no effect on the burning rate. Similar burning rate work was done in connection with an investigation on the flame structure of solid propellants [304].

The strand burning rates of TAGN and 3,6-diguanidino-1,2,4,5-tetrazine nitrate (DGTN), their combustion wave structure, and the location and chemical nature of the leading reaction on combustion were determined in a windowed 1.5-L constant pressure bomb with 7-mm diameter and 12–15-mm long samples pressed into acrylic tubes [306]. Temperature profiles in the combustion wave were measured using thin tungsten/rhenium thermocouples. Both compounds have the same structural fragment, i.e., the protonated guanidine moiety, which may result in similar combustion mechanisms. The burning rate of TAGN increased steadily as the pressure increased up to 2 MPa, showing a pressure exponent of 0.94. A kind of burning instability region set in at 2 MPa, characterized by a constant burning rate, which began to increase again at pressures higher than 4 MPa. Thermocouple measurements showed the similar surface temperatures for both salts. It was shown that combustion of both substances

obeyed the condensed-phase mechanism. The higher burning rate of TAGN connected with the higher decomposition rate in the melt layer.

#### 14.1.5 Toxicity of Triaminoguanidinium Nitrate

The LD<sub>50</sub>/14 d of TAGN in mice was 3.65 g/kg with 95% confidence limits of 3.54 to 3.76 g/kg [307]. Guanidine and derivatives of guanidine were reported to produce effects on the automatic nervous system and the neuromuscular junction. Therefore, a study was conducted to screen TAGN for effects on the physiological function of these peripheral nervous systems. Dogs were anesthetized and surgically instrumented to measure and record arterial blood pressure, lead II electrocardiogram (ECG), heart rate, contraction of the nictitating membrane upon vagus nerve stimulation, and contraction of the gastrocnemius muscle upon sciatic nerve stimulation. Intra-venous doses of 50–200 mg TAGN/kg given to anesthetized dogs caused a slightly decreased heart rate and a transient fall in arterial blood pressure followed by a slight increase. In these animals, TAGN did not alter the function of the peripheral autonomic nervous system or the neuromuscular junction. The duration of these effects was 20 to 25 minutes. TAGN belongs in the category of slightly toxic compounds.

The toxicologic and recalcitrant properties of TAGN were investigated by exposing pure cultures of microorganisms to TAGN [308]. The results indicated that while TAGN was generally bacteriostatic at concentrations of 100 ppm and above, the bacteria tested were not otherwise adversely affected by concentrations as high as 2000 ppm for contact periods up to 5 h. Under the experimental conditions of this study, TAGN was neither bactericidal nor did it appreciably affect the respiratory activity of the cells. Following exposure and subsequent removal of TAGN from solution, all bacteria tested were capable of normal growth resumption. Moreover, some bacteria were capable of degrading or at least removing TAGN from solution, thereby effectively reducing the aqueous concentration of this compound.

As a next step, a study was undertaken to examine the gaseous by-products generated from the deflagration of an experimental TAGN-based gun propellant and to compare the toxicity of these gases to those produced from standard gun propellants containing no TAGN [309]. Gas analysis results showed that TAGN-based propellants produced the same gaseous by-products as did four standard nitrocellulose (NC)-based propellants. However, quantitative differences in the response of bacteria were observed between the two groups.

The toxic effects of TAGN on the fruit fly *Drosophila melanogaster* were determined by administering the chemical via their growth medium [310]. Toxicological and reproductive effects were determined at concentrations up to 4000 ppm TAGN. Increasing the concentration of TAGN to 1000 ppm in the medium resulted in almost all cessation of pupae and larvae production, as well as approximately 50% death of adult *Drosophila*. Concentrations of 2000 ppm TAGN and above resulted in the death of almost all adult *Drosophila*. Concentrations of these levels are considered to be relatively

high, however, for practical use. Compared to other propellant ingredients, TAGN appeared to be relatively non-toxic to *Drosophila*.

TAGN was subjected to a matrix of *in vitro* assays employing microbial cells, mammalian cells in culture, and *in vivo* tests measuring potential germ cell effects in mice and rats [311]. TAGN was mutagenic and produced DNA damage in the *in vitro* assays. The response was obtained without the presence of an *in vitro* activation system, indicating that the TAGN molecule has genetic activity. No significant induction of dominant lethal effects was observed in either mice or rats. TAGN should be considered a suspect compound in terms of mutagenic and carcinogenic potential. The combined positive results from all *in vitro* assays indicated a high probability for carcinogenic activity.

Triaminoguanidinium nitrate was tested for teratogenicity in rats and administered by intra-peritoneal injections at doses of 0, 200, 400, and even 800 mg/kg during days 6–15 of gestation [312]. At the highest dose, most litters were entirely resorbed. In the highest dose group (800 mg/kg), three rats died during the dosing regimen and only one viable litter was obtained. The lower dose caused an increased incidence of runting and perinatal death. An increase in malformations due to TAGN was not observed.

#### 14.1.6 Environmental Fate of Triaminoguanidinium Nitrate Spills

The biodegradability of TAGN and wastewater from TAGN production was determined under a variety of environmental conditions [313, 314]. Supplemental carbon was required in order for biodegradation to occur under aerobic or anaerobic conditions. Although TAGN is biodegraded under both aerobic and anaerobic conditions, the nitrate portion of the salt will only degrade anaerobically (denitrification). The alternate carbon (e.g., sugar) is required for this process as well. TAGN was found to be unstable under alkaline conditions, resulting in the formation of carbohydrazide (diaminourea). No intermediates were identified during this process. No urea, guanidine cyanamide, cyanoguanidine, cyanoguanidine, or hydrazine were detected during the biodegradation of TAGN.

#### 14.1.7 Safety Properties of Triaminoguanidinium Nitrate

Triaminoguanidinium nitrate, when dry, is a class A or class 1.1 explosive with an impact sensitivity of approximately 45 kg-cm, and therefore presents a safety hazard for handling, transportation, and storage. TAGN is usually shipped and stored while wet with water or alcohol to reduce accidental ignition hazards. TAGN has been shipped wet with 20% water and some reports (Teledyne McCormick Selph MSDS) state that in two tests, the 20% water sample failed to initiate with a No. 6 blasting cap. However, there is concern that the water may evaporate and that the material could become more sensitive in transit. Other manufacturers have shipped TAGN wet with 2-propanol, but the material turned pink during storage.

The impact sensitivity of TAGN in the BAM machine is 4 N m. For comparison, the impact sensitivity of RDX in the same machine is 7.5 N m. The friction sensitivity of dry TAGN in the BAM machine is above a pistil load of 120 N, where crackling noises begin to be heard. For comparison, the friction sensitivity of RDX in the same machine is 120 N pistil load.

Table 28 gives a comparison of the increase in drop-weight sensitivity (decrease of the drop height resulting in ignition) of a series of guanidinium and guanidinium derivative salts with progressive replacement of amino groups with hydrazino groups. As can be seen from these data, the hydrazino compounds are more sensitive than the amino compounds.

**Table 28:** Drop-weight sensitivity of guanidinium and guanidine derivative salts.

| Compound name                   | Formula                                                                              | Drop-weight sensitivity, Bureau of Mines apparatus, 2 kg |
|---------------------------------|--------------------------------------------------------------------------------------|----------------------------------------------------------|
| Guanidinium nitrate             | $[\text{C}(\text{NH}_2)_3]^+\text{NO}_3^-$                                           | 100                                                      |
| Diaminoguanidinium nitrate      | $[\text{H}_2\text{NC}(\text{NHNH}_2)_2]^+\text{NO}_3^-$                              | 40                                                       |
| Triaminoguanidinium nitrate     | $[\text{C}(\text{NHNH}_2)_3]^+\text{NO}_3^-$                                         | 28                                                       |

| Tetryl                          | $(\text{NO}_2)_3\text{C}_6\text{H}_2\text{N}(\text{CH}_3)\text{NO}_2$                | 26                                                       |

Data source: [244]

#### 14.1.7.1 Explosive Properties of Triaminoguanidinium Nitrate

TAGN can be used as an explosive [274]. Confined TAGN had a detonation velocity of 5300 m/s at a packing density of 0.95 g/cm<sup>3</sup>, 7930 m/s at a packing density of 1.46 g/cm<sup>3</sup>, and of 5350 m/s at a packing density of 1.00 g/cm<sup>3</sup>. The corresponding triaminoguanidinium perchlorate has a detonation velocity of 7730 m/s at a packing density of 1.56 g/cm<sup>3</sup> and 5970 m/s at a packing density of 1.09 g/cm<sup>3</sup>. In the lead block test, explosion of TAGN caused an increase in the cavity volume by 350 cm<sup>3</sup>/10 g TAGN.

#### 14.1.8 Applications of Triaminoguanidinium Nitrate

The current chapter is limited to a summary of the physical, chemical, and safety properties of TAGN. There are many applications of TAGN that are discussed in other chapters of this book. Triaminoguanidinium nitrate is used in many propellant and gas

generant formulations because of its ability to lower the flame temperature and yet maintain high performance due to its high hydrogen and low carbon content. Applications of TAGN as a rocket propellant ingredient and in gas generants will be discussed in a future set consisting of several volumes on solid propellants and gas generants, to be published as part of the *Encyclopedia of Rocket Propellants*. Triaminoguanidinium nitrate is an essential ingredient in some gun propellants, gas generants, and pyrotechnic compositions, as well as in “green” double-base and composite rocket propellants. It enables lower molecular weight gases and reduced flame temperatures concomitant with increased impetus and muzzle velocity in guns. TAGN can also be used as an effective activator and burning rate modifier for AN-based propellants and cyclic nitramine (RDX) propellant formulations. The increased reactivity of TAGN in those propellant formulations limits the choice of binders, curing agents, and plasticizers.

There are hundreds of patents for propellant and gas generant compositions containing TAGN, which cannot all be cited here. It seems that some of the claims were farfetched and only rarely is experimental proof provided as part of the patent’s specifications.

Low-molecular-weight GAP oligomers have been used as energetic plasticizers, in particular for propellants with ingredients like TAGN that are not compatible with nitrate ester energetic plasticizers. One type of propellants used TAGN with a GAP plasticizer [315].

## 14.2 Triaminoguanidinium Perchlorate

### 14.2.1 Preparation of Triaminoguanidinium Perchlorate

Triaminoguanidinium perchlorate, also known as TAGP,  $\text{TAGClO}_4$ ,  $(\text{TAGH})\text{ClO}_4$ , 1,2,3-triaminoguanidinium perchlorate  $[(\text{H}_2\text{NNH})_3\text{C}^+]\text{ClO}_4^-$ ,  $\text{CH}_9\text{N}_6\text{O}_4\text{Cl}$ , triaminoguanidine perchlorate; carbonohydrazonic dihydrazide, perchlorate (1:1); carbonohydrazonic dihydrazide, monoperchlorate; guanidine, 1,2,3-triamino-, monoperchlorate; dihydrazinomethylenehydrazinium perchlorate, CAS RN [4104-85-2], can be prepared from aminoguanidinium bicarbonate with perchloric acid (first giving the aminoguanidinium perchlorate) followed by reaction with hydrazine hydrate. Another method is reaction of one mol of guanidinium perchlorate with three mols of hydrazine in isopropanol solution. Another method is the reaction of triaminoguanidine free base and perchloric acid in dilute solutions [316].

### 14.2.2 Physical Properties of Triaminoguanidinium Perchlorate

Triaminoguanidinium perchlorate was synthesized by nucleophilic attack of aqueous hydrazine solution on aminoguanidinium perchlorate under release of ammo-

nia [5]. TAGClO<sub>4</sub> has the highest melting point (398 K = 125 °C) among three similar compounds investigated, which can be explained by the many hydrogen bonds holding together its crystal structure. The onset of exotherm in the DSC is at 453 K (180 °C).

Other sources list the melting point of TAGP as 407–408 K (134–135 °C) and the maxima of the exotherm peaks in the DTA are at 516 and 590 K (243 and 317 °C), accompanied by violent decomposition [172].

TAGClO<sub>4</sub> is less stable than AGClO<sub>4</sub>, which is more stable and decomposes at 523 K (250 °C). The structure of the perchlorate salt in the crystalline state was determined using low-temperature single-crystal XRD, indicating a monoclinic structure. The crystallographic data of aminoguanidinium, triaminoguanidinium, and azidoformamidinium perchlorate are summarized in Table 22 (in Section 12.2 “Aminoguanidinium Perchlorate”). Further information regarding the crystal structure determinations has been deposited with the Cambridge Crystallographic Data Centre [317]. The geometry of the cation is comparable to those reported for triaminoguanidinium chloride and nitrate in the literature. Again, the positive charge is delocalized, which can be seen by the similar C–N bond lengths building a planar fragment. The hydrazine N–N bonds have similar lengths between 1.40 and 1.42 Å. The layer packing is influenced by several N–H···O and N–H···N hydrogen bonds, resulting in a high density of 1.740 g/cm<sup>3</sup>. TAGClO<sub>4</sub> was characterized using multinuclear (<sup>1</sup>H, <sup>13</sup>C, and <sup>15</sup>N) NMR spectroscopy. The <sup>15</sup>N NMR and <sup>13</sup>C NMR chemical shifts of TAGClO<sub>4</sub> (in ppm) are δ(N1)–289.1, δ(N2)–329.4, δ(N3)–289.1, δ(N4)–329.4, δ(N5)–289.1, δ(N6)–329.4, and δ(C1) 159.5. The IR (ATR, cm<sup>–1</sup>) wave numbers are ν = 3293(vs), 1680(s), 1359(w), 1218(w), 1056(s), 955(m), 936(m), 707(w), and 618(m), and the Raman (excited with 1064 nm) lines (in cm<sup>–1</sup>) are 3363 (8), 3305 (17), 1686 (4), 1638 (2), 1361 (2), 1146 (4), 937 (100), 890 (15), 626 (13), 461 (18), 414 (7), and 260 (7). The enthalpy of formation of crystalline TAGClO<sub>4</sub> is +121 ± 17 kJ/mol. The enthalpy of formation of TAGClO<sub>4</sub> in aqueous solution is +36.3 kJ/mol (+8.68 kcal/mol).

The IR spectrum of TAGP (from a different source) is shown in Figure 32.

The crystal structure of TAGP was determined by single-crystal XRD [316]. The results showed that TAGP crystals belong to the monoclinic system with space group *P*2<sub>1</sub>/*c* and cell parameters of *a* = 1.0213(11) nm, *b* = 1.4869(15) nm, *c* = 1.0936(11) nm, and β = 102.91(2)°. TAGP was characterized by elemental analysis, FTIR, DSC, and DTA/TGA. The TGA results showed that the title compound lost 99.7% mass at 730 K (457 °C) with a heating rate of 10 °C/min.

Triaminoguanidinium chloride may not be useful as a rocket propellant, but it may be used as an intermediate in the synthesis of other TAG salts; therefore, its crystal structure has been determined just to see how it differs from that of other TAG salts [318]. The hexagonal structure (*P*6<sub>3</sub>/*m*) has unit cell dimensions: *a* = *b* = 7.480(1) Å and *c* = 6.218(1) Å. The structure consists of layers of ions parallel to (001) located at + or –1/4 *c*, held together by van der Waals forces. The C–N bond length is 1.325(2) Å and the N–N bond length is 1.411(4) Å, which agrees quite well with the bond lengths found

**Figure 32:** Infrared spectrum of triaminoguanidinium perchlorate. (Reproduced and modified from [21].)

in TAGN. The heat of formation of triaminoguanidinium chloride in aqueous solution is +5.1 kJ/mol (+1.23 kcal/mol) [279, 280].

#### 14.2.3 Safety Properties of Triaminoguanidinium Perchlorate

Triaminoguanidinium perchlorate is a potential rocket propellant, gas generant, and explosive ingredient, but it is very hygroscopic and very sensitive to impact and friction [243]. The drop-weight impact sensitivity 50% point is at only 7 cm with a 2-kg weight (compared to 17 cm for PETN), which means it is very sensitive to accidental ignition and explosion by mechanical shock.

Similar applications in explosives have been suggested for diaminoguanidinium perchlorate and diaminoguanidinium picrate [243]. The impact sensitivity of triaminoguanidinium perchlorate can be reduced by addition of lithium perchlorate.

If triaminoguanidinium perchlorate were to be used as an oxidizer in solid composite propellants, its particle size would have to be reduced to achieve high burning rates. Grinding TAGP is virtually impossible due to the high friction and impact sensitivity of the dry material. It has therefore been suggested to convert TAGP to a solid solution by forming a low-melting eutectic with  $\text{LiClO}_4$ . The eutectic mixture containing 35% TAGP and 65%  $\text{LiClO}_4$  melts at 355 K (82 °C) and has an impact sensitivity of 20 cm with a 2-kg weight, thus it is less sensitive than pure TAGP. The eutectic containing 65% TAGP and 35%  $\text{LiClO}_4$  is a liquid at room temperature. Such low-melting oxidizers could be homogeneously mixed with the monomer binder prior to polymerization and would enable very uniform oxidizer distribution throughout the polymerized grain and high solids loading [319]. TAGP: $\text{LiClO}_4$  ratios of 65:35 to 35:65 were recommended for such solid solutions with polyacrylamide or polymethylacrylamide binders.

The impact sensitivity of  $\text{TAGClO}_4$  as tested in the BAM fall hammer machine is 3 N m and the friction sensitivity is 45 N. It is more sensitive than  $\text{AGClO}_4$ .

#### 14.2.4 Explosive Performance of Triaminoguanidinium Perchlorate

Triaminoguanidinium perchlorate has a detonation velocity of 7730 m/s at a packing density of  $1.56 \text{ g/cm}^3$  and of 5970 m/s at a packing density of  $1.09 \text{ g/cm}^3$  [274].

### 14.3 Triaminoguanidinium Dinitramide

Triaminoguanidinium dinitramide, also known as triaminoguanidinium dinitramide, 1,3,5-triaminoguanidinium dinitramide; carbonohydrazone dihydrazide, compd. with *N*-nitronitramide (1:1);  $[(\text{H}_2\text{NNH})_3\text{C}^+][\text{N}^-(\text{NO}_2)_2]$ , TAGDN,  $\text{C}_1\text{H}_9\text{N}_9\text{O}_4$ , CAS RN [252062-65-0P], with a molecular mass of 211.14 g/mol and an oxygen balance of  $-18.94\%$  melts at 360 K (87 °C) [131].

The energetic compound 1,3,5-triaminoguanidinium dinitramide was prepared in good yield (82%) and fully characterized by single-crystal XRD, IR and Raman spectroscopy, multi-nuclear NMR spectroscopy, MS, and elemental analysis as well as thermal and mechanical sensitivity (DSC, thermal calorimetry, impact, friction, and ESD sensitivity tests) [320].

For the heats of combustion, enthalpies of formation, and enthalpies of solution of triaminoguanidinium dinitramide, see Table 13 in section “Guanidinium Dinitramide” and for the same data plus theoretical detonation performance data, see Table 29 in the “Other Triaminoguanidinium Salts” section.

Two dinitramide salts with a very high heat of formation, i.e., triaminoguanidine dinitramide (TAGDN, CAS RN [252062-65-0P]) and guanylazide dinitramide (GADN, CAS RN [639818-61-4P]), were evaluated as propellant ingredients [321]. The density of crystalline TAGDN is  $1.57 \text{ g/cm}^3$ , which is in the same range as the density of the free base itself ( $1.521 \text{ g/cm}^3$ ) and TAGN ( $1.594 \text{ g/cm}^3$ ). Thermochemical calculations showed that TAGDN propellants have a higher impetus than the corresponding GADN propellants at a given flame temperature. The melting point and enthalpy of melting of TAGDN was found to be 358 K (85 °C) and 93 J/g, respectively. At a heating rate of 10 K/min, TAGDN started to decompose at approximately 433 K (160 °C; Figure 33).

Preliminary sensitivity testing of crystalline TAGDN indicated that it was very sensitive to friction. Therefore, TAGDN was prilled by a melt-emulsion technique to form spherical particles. However, this procedure did not decrease the sensitivity. Due to its high sensitivity, TAGDN should be handled with care, and it is questionable whether it can ever be used in solid propellants. The solubility of TAGDN in water was measured to evaluate it as an energetic component in liquid monopropellants, but the solubility of TAGDN is low, and, therefore, TAGDN is less attractive than ADN for liquid monopropellants.

**Figure 33:** DSC and TGA curves for TAGDN. (Republished and modified from [321], with permission from ©2003 John Wiley Sons; permission conveyed through Copyright Clearance Center.)

If the heat of formation of a nitrate (XN) is known, it seems possible in many cases to calculate the heat of formation of the corresponding dinitramide (XDN) by the following equation:

$$\Delta H_f \text{XDN} = \Delta H_f \text{XN} + 230n \left( \frac{\text{kJ}}{\text{mol}} \right)$$

where  $n$  is the number of anions per cation. Applying this formula to TAGN and TAGDN gives a predicted standard enthalpy of formation for TAGDN of +184 kJ/mol.

Some of the most promising candidates for high-nitrogen compounds are triaminoguanidinium dinitramide and triaminoguanidinium 1-methyl-5-nitrimino-tetrazolate [322, 323]. They are even evaluated as potential replacements for RDX.

#### 14.4 Triaminoguanidinium Nitroformate

Triaminoguanidinium nitroformate, TAGNF, was one of four guanidine derivative nitroformate compounds prepared and characterized by a group of researchers at the University of Munich in Germany [193, 195]. The physical and sensitivity properties of TAGNF are summarized in Tables 14 and 16 above. As opposed to AGNF and DAGNF, which already decompose to the corresponding nitrate salts when standing in aqueous solution at room temperature, TAGNF is quite stable and can be stored indefinitely. The theoretically predicted values for the velocity of detonation and the detonation

pressure for ANF, HNF, MNF, GNF, AGNF, DAGNF, and TAGNF all lie within the range expected for high explosives such as RDX, and some are even superior to TNT, while at the same time releasing larger amounts of gaseous decomposition products and having a more favorable oxygen balance. Of all the compounds listed in Tables 10 and 13, HNF has the highest predicted values for detonation pressure (380 kbar) and the velocity of detonation (9286 m/s), whereas ANF shows the most positive oxygen balance with a value of +19%. Of the compounds listed in Tables 14 and 16, TAGNF is not only thermally more stable compared to AGNF and DAGNF (which decompose on standing at room temperature after several hours), but it also shows the highest predicted values for the detonation pressure (330 kbar) and the velocity of detonation (8982 m/s). TAGNF has the highest positive heat of formation (+59.1 kcal/mol) in this group.

Another salt similar to TAGNF which should be examined is the di-TAG salt of tetranitroethane (TAGTE). TAGTE has a high oxygen to carbon ratio (2 to 1) and good physical properties.

### 14.5 Triaminoguanidinium Azide

Triaminoguanidinium azide, also known as 1,2,3-triaminoguanidinium azide; hydrazoic acid, compound with 1,2,3-triaminoguanidine (1:1); TAG azide, TAZ, TAGZ, "TAGA,"  $[(\text{H}_2\text{NNH})_3\text{C}^+]\text{N}_3^-$ ,  $\text{CH}_9\text{N}_9$ , triaminoguanidine azide, CAS RN [15067-49-9], with a molecular mass of 147.15 g/mol (6.795 mol/kg), can be prepared in 70% yield by reaction of triaminoguanidinium sulfate with sodium azide in dilute alcohol and filtering out the insoluble sodium sulfate [324]. A product made by this method will contain some sodium sulfate as a contaminant. Triaminoguanidinium azide was tested as a rocket propellant at Atlantic Research Company under contract AF33(616)6623 as early as 1961. Propellants containing TAG azide, beryllium, and beryllium hydride were supposed to achieve specific impulse ( $I_{\text{sp}}$ ) values close to 300 s. One of the oxidizers considered was hydrazinium nitroformate (HNF). This is one of the first mentions of HNF as a rocket propellant. Only several decades later did HNF undergo renewed examination as a rocket propellant.

Using a cation-exchange technique in non-aqueous solvents, TAG azide can be prepared from TAG<sup>+</sup>-loaded ion-exchange resin and a methanolic solution of sodium azide [325, 326]. A lightly cross linked, strong acid cation resin was loaded with TAG ion by passing an excess aqueous solution of TAGN slowly through the column. After the TAGN feed solution was depleted, the column was rinsed with deionized water until the effluent had a pH of 7 (neutral). Water and dissolved oxygen were removed by displacement of the water by an excess of anhydrous methanol that had previously been deaerated by boiling and cooling under nitrogen gas. Triaminoguanidinium azide was then eluted from the column with an oxygen-free anhydrous methanolic solution of sodium azide. The effluent was protected from air oxidation by collection under a layer of iso-octane (or any inert non-polar liquid).

Overnight refrigeration of the protected effluent resulted in the precipitation of white TAGZ crystals which were filtered and dried under vacuum. The product initially obtained by this method was white and quite hygroscopic. The product did not rapidly discolor when exposed to dry air, but would rapidly change color in humid air. This suggests that pure TAGZ is relatively stable to dry air, but is highly reactive in moist air. This method works in non-aqueous solutions and facilitates removal of the solvent at the end of the process. The X-ray density of TAGZ is  $1.45 \text{ g/cm}^3$ . The enthalpy of formation is  $+414 \text{ kJ/mol}$  ( $+99 \text{ kcal/mol}$ ). The oxygen balance of TAGZ is  $-70.68\%$ . It has a positive heat of formation  $\Delta H_f = +464 \text{ kJ/mol} = +110.9 \text{ kcal/mol}$  and a high nitrogen content =  $85.70\% \text{ N}$ . The FTIR spectrum exhibited stretching frequencies at  $2100 \text{ cm}^{-1}$  ( $-\text{N}_3$ ) and at  $3400 \text{ cm}^{-1}$  ( $-\text{NH}_2$ ). TAGZ is less impact and friction sensitive than other conventional nitrogen-rich compounds. The drop-weight impact height for 50% explosion for TAGZ is 170 cm and the friction insensitivity is  $36 \text{ kg}_f$ .

A disadvantage of the reaction of TAGN with  $\text{NaN}_3$  is that it may leave some solid impurities like  $\text{NaN}_3$  unreacted and the by-product,  $\text{NaNO}_3$ , as contaminant in the final product. An alternate method to the reaction of TAGN with  $\text{NaN}_3$  with a cation-exchange resin is preparation of TAGZ in non-aqueous medium by reaction of triaminoguanidine free base with hydrazoic acid solution formed by ion-exchange resin and  $\text{NaN}_3$  [327]. The reaction of H-loaded sulfonate resin and  $\text{NaN}_3$  in methanol can produce  $\text{HN}_3$  in solution, which is easy to neutralize with a solution of triaminoguanidine free base and the salt then precipitates out. See also [328].

Triaminoguanidinium azide forms a double salt with hydrazinium azide, frequently abbreviated as THA. The THA salt is obtained in 58% yield from triaminoguanidinium sulfate, hydrazinium sulfate, and sodium azide in methanol solution [329]. This compound with a gross formula of  $\text{CH}_{14}\text{N}_{14}$  has a density of  $1.46 \text{ g/cm}^3$  and a heat of formation of  $665 \pm 4 \text{ kJ/mol}$  ( $158.9 \pm 1 \text{ kcal/mol}$ ). It is sensitive to impact (50% fire at 17.5 cm with a 2-kg weight) and decomposes at 423 K.

TAG azide forms another double salt with TAGN called TAZN, which crystallizes as orthorhombic (space group *Pbca*) crystals with  $a = 12.647(3) \text{ \AA}$ ,  $b = 6.573(2) \text{ \AA}$ , and  $c = 16.550(7) \text{ \AA}$  [330, 331]. Azide and nitrate ions are randomly distributed over eight general positions in the space group *Pbca* crystal lattice. This compound forms as a contaminant if nitrate ion is present during the preparation of TAG azide. The calculated X-ray density was  $1.52 \text{ g/cm}^3$ . Elemental analysis indicated that this compound contained 9.53% carbon, 78.17% nitrogen, 5.78% hydrogen, and, unexpectedly, 6.15% oxygen. In contrast, TAZ theoretically contains 8.16% carbon, 85.71% nitrogen, and no oxygen.

When making triaminoguanidinium azide by reaction of sodium azide with a cation-exchange resin, it was inevitable to leave some solid impurities like unreacted  $\text{NaN}_3$  and the by-product  $\text{NaNO}_3$  in the final product, and the yield of TAGZ was only 23% based on TAGN. In order to avoid this problem, TAGZ was synthesized

in non-aqueous medium by the reaction of free triaminoguanidine (TAG) with fresh  $\text{HN}_3$  solutions formed by ion-exchange resin and  $\text{NaN}_3$ , [332]. The neutralization of TAG with  $\text{HN}_3$  should be theoretically complete, but the yield of TAGZ was only 73.5% and 50% based on TAG and TAGN, respectively.

The enthalpy of formation of TAGZ is  $+718 \text{ cal/g} = +105.6 \text{ kcal/mol} = +442 \text{ kJ/mol}$  and the density is  $0.0520 \text{ lb/in.}^3 = 1.439 \text{ g/cm}^3$  [124].

#### 14.5.1 Thermal Decomposition of Triaminoguanidinium Azide

The thermal decomposition of TAGZ consisted of a four-stage heat-generation and mass-loss process when measured by DTA-TGA as shown in Figure 34 [134]. The first stage corresponded to the endothermic reaction observed in TGA between 363.6 and 416 K (90.45 and 143 °C), corresponding to 28.17% weight loss. The second stage corre-

**Figure 34:** DTA-TGA thermogram of triaminoguanidinium azide. (Republished and modified from [134], with permission of ©2009 Elsevier Science Technology Journals; permission conveyed through Copyright Clearance Center Inc.)

sponded to an endothermic melting phase change from solid to liquid at 445 K (172 °C), followed by a rapid exothermic reaction between 445 and 450 K (172 and 177 °C) accompanied by a 30.70% weight loss. The third stage corresponded to endothermic decomposition between 450 and 587 K (177 and 314 °C), corresponding to 24.34% weight loss, and the fourth stage corresponded to a very slow endothermic reaction at the higher temperature (beyond 587 K [314 °C]) with 13% weight loss. DTA experiments indicate that TAGZ decomposed endothermically at the first stage, indicating the cleavage of  $\text{HN}_3$  at 388 K (115 °C). It underwent endothermic melting of the products at 445 K (172 °C) followed by rapid exothermic decomposition at up to 478 K (205 °C). Thereafter, it underwent a very slow endothermic decomposition. Similar data were obtained by DSC (Figure 34). The DSC thermogram showed that the decomposition of TAGZ took place with two endotherms and one exotherm. The first endotherm appeared between 363 and 416 K (90 and 143 °C), with a peak temperature at 388.3 K (115.2 °C). The second endotherm took place between 423 and 450 K (150 and 177 °C), with a peak temperature at 442.8 K (169.7 °C), whereas the exotherm appeared between 450 and 478 K (177 and 205 °C) with a peak temperature at 459 K (185.9 °C).

If TAGZ is heated to 453 K, it forms a polymer by auto-condensation and loss of hydrazine [333].

#### 14.5.2 Applications of Triaminoguanidinium Azide

The use of TAGZ in CMDB propellants has been patented [334]. Other applications are in pyrotechnic disseminating gas generators, where an excessively hot disseminating gas would damage the material (e.g., a chemical warfare agent) to be disseminated [335]. In other applications of TAGZ, it is advantageous that the exhaust of the rocket is so cool that it does not interfere with radio signal transmission [336].

### 14.6 Other Triaminoguanidinium Salts

The triaminoguanidinium cation is already a key component in high-nitrogen compounds. The nitrogen content can be increased further by combining it with nitrogen-rich anions.

Upon encountering a high-nitrogen compound containing a triaminoguanidinium cation and a tetrazolate anion, should we reference it here in Section 14 or in chapter “Heterocyclic and Heterocyaloaliphatic Amines” in Section 10 on tetrazole derivatives? In accordance with the rules established at the beginning of this chapter, salts are arranged by the cations first, and the compound is treated here as a triaminoguanidinium salt.

### 14.6.1 Triaminoguanidinium 5-Aminotetrazolate

A solution of the free triaminoguanidine base in methanol can be used to synthesize a number of high-nitrogen compounds, such as triaminoguanidinium 5-aminotetrazolate,  $C_2H_{11}N_{11}$ , by direct reaction of TAG with 5-AT [337]. The crystallized product first obtained is a hemihydrate that can be dehydrated by keeping it in a vacuum desiccator above  $P_2O_5$  at 353 K for 18 h. The dry product melts at 414–415 K (141–142 °C). Triaminoguanidinium 5-aminotetrazolate contains 81.5 mass-% nitrogen, is thermally stable below 403 K (130 °C), and is hygroscopic. The density of triaminoguanidinium 5-aminotetrazolate is  $\rho = 1.525 \text{ g/cm}^3$  and the heat of formation is  $\Delta H_f = +356 \text{ kJ/mol} = +85 \text{ kcal/mol}$ .

Bis(1,2,3-triaminoguanidinium) bis(5-aminotetrazolate) monohydrate,  $2[CH_9=N_6^+]\bullet 2[CH_2N_5^-]\bullet H_2O$ ,  $M = 396.4$ , is a high-nitrogen compound [338]. It crystallizes in monoclinic space group  $C2/c$  crystals with  $a = 10.448(2) \text{ \AA}$ ,  $b = 10.387(1) \text{ \AA}$ ,  $c = 15.544(3) \text{ \AA}$ ,  $\beta = 93.11(1)^\circ$ ,  $V = 1684.4(5) \text{ \AA}^3$ ,  $Z = 4$ ,  $\rho = 1.56 \text{ g/cm}^3$ .

### 14.6.2 Bis(triaminoguanidinium) 5,5'-Azotetrazolate

Bis(triaminoguanidinium) 5,5'-azotetrazolate, also known as di(triaminoguanidinium) 5,5'-azotetrazolate, TAGzT, TAGAT,  $C_4H_{18}N_{22}$ ,  $C_2H_2N_{10}\bullet 2CH_8N_6$ , CAS RN [2165-23-3], is a unique energetic high-nitrogen compound that has received a lot of attention during the past two decades. TAGzT is also described in CAS as “carbohydrazonic dihydrazide, compound with 5,5'-(1,2-diazenediyl)bis[2H-tetrazole] (2:1).”

Triaminoguanidinium azotetrazolate (TAGAT) is an energetic material with one of the highest nitrogen contents (82.3 mass-% N). The friction sensitivity in the Julius Peters apparatus is 230 N. The drop-weight sensitivity with a 2-kg mass is  $H_{50} = 25 \text{ cm}$ . The ESD sensitivity is 0.312 J.

Additional TAGzT properties are listed in Section 10 “Tetrazoles” of chapter “Heterocyclic and Heterocycloaliphatic Amines.” The density of TAGzT is  $1.6 \text{ g/cm}^3$  and the enthalpy of formation is  $+1076 \text{ kJ/mol}$  ( $+257 \text{ kcal/mol}$ ).

Bis-triaminoguanidinium azotetrazolate (TAGAT, TAGzT,  $C_4H_{18}N_{22}$ ) has been evaluated as an additive to gun propellants to reduce barrel wear. TAGzT has been evaluated as an additive to and/or as a replacement for RDX in nitramine propellants. The strand burning rates of mixtures of TAGzT and RDX showed a peculiar behavior which necessitated a more in-depth investigation. Because this compound is a salt of an amide cation with a heterocyclic amine anion, it is also described in more detail in

chapter “Heterocyclic Amines.” The burning rate and sensitivity depend on the particle size of the material, which is not very soluble in most common solvents. A variety of solvents were evaluated to find the best solvent for recrystallization of TAGzT to obtain crystals with a controlled crystal size [339].

The thermal decomposition of TAGzT was investigated by TGA, DSC, gas (solid) *in-situ* thermolysis, and rapid-scanning FTIR [340]. The results showed that thermal stability of TAGzT can reach up to 473 K (200 °C). The thermal decomposition of TAGzT was insensitive to pressure. The condensed-phase products at 738 K (465 °C) consisted of carbon black,  $\text{NH}_4\text{N}_3$ , and melem. The thermal decomposition kinetic parameters and kinetic rate equations of TAGzT were obtained from the DSC data, and a thermal decomposition mechanism for TAGzT was proposed.

The thermal decomposition characteristics of triaminoguanidinium azotetrazolate (TAGzT), 3,6-bis(1*H*-1,2,3,4-tetrazol-5-yl-amino)-1,2,4,5-tetrazine (BTATz), and 3,6-diamino-1,2,4,5-tetrazine-1,4-dioxide (LAX-112) were studied by DTA, DSC, high-pressure DSC, TGA-DTA, and T-jump/FTIR [341]. The thermal decomposition kinetic parameters, the  $E_a$  and  $\log A$  values, of TAGzT, BTATz, and LAX-112 were 231.87, 317.41, and 175.62 kJ/mol, and 25.01, 28.07, and 16.20 s<sup>-1</sup>, respectively.

The thermal decomposition products of three high-nitrogen compounds, triaminoguanidinium azotetrazolate (TAGzT or TAGAT), guanidinium azotetrazolate (GUzT), and 3,3'-diamino-4,4'-azoxyfurazan (DAAF), were analyzed on-line by MS to identify the weak links in the molecules so that in the future, new compounds could be synthesized that avoided these weak links [342]. The fragments allow one to backtrack to where they came from. The TAGzT decomposition showed a product distribution consisting of three temperature-correlated  $m/z$  groups: group I:  $\text{C}_2\text{H}_y\text{N}_z$  ( $z = 2, 3$ , or  $4$ ),  $\text{C}_3\text{H}_y\text{N}_z$  ( $z = 4$ , or  $5$ ), and  $\text{H}_y\text{N}_z$  ( $z = 1$ , or  $2$ ) evolving from 453–478 K (180–205 °C); group II:  $\text{C}_1\text{H}_y\text{N}_z$  ( $z = 3$ , or  $4$ ) and  $\text{C}_2\text{H}_y\text{N}_z$  ( $z = 4$ , or  $5$ ) evolving from 453–553 K (180–280 °C); and group III:  $\text{C}_3\text{H}_y\text{N}_z$  ( $z = 5$  or  $6$ ) evolving from 493–553 K (220–280 °C). Products from GUzT decomposition could be separated into three  $m/z$  groups which evolved in three stages from 485–528 K (212–255 °C), from 493–533 K (220–260 °C), and from 488–533 K (215–260 °C). The DAAF decomposition products showed a broad temperature range variation under low and high confinement in the overall range from 393 to 543 K (120 to 270 °C). For comparison, RDX was tested under the same conditions, and it decomposed between 483–533 K (210–260 °C).

The thermal decomposition of TAG-based salts and their interaction with RDX were examined over a range of conditions that are relevant to performance, safety, and long-term aging behavior of gun propellants [343]. Four TAG-based salts (TAGzT, TAG-TATTz, TAG nitrate, and TAG chloride) have been examined to investigate the role of the anion in the reaction network. The reaction networks of TAG-TATTz and TAGN have features similar to those found in previous studies of TAGzT. The relative fraction of hydrazine observed in the four salts when examined by themselves has the following sequence: TAGzT TAG-TATTz TAGN TAGCl, indicating that the smaller inorganic anions,  $\text{Cl}^-$  and  $\text{NO}_3^-$ , are more reactive than the organic anions. Reactions of TAGzT,

TAG-TATTz, and TAGN with RDX showed that the extent of reaction of hydrazine with RDX is comparable for each salt. This suggested that even though the inorganic anions react more readily with hydrazine than the organic anions, the rate of reaction of hydrazine with RDX is faster than its rate of interaction with the anions. The reaction of hydrazine with RDX occurred primarily in the gas phase. The initial reaction for thermal decomposition of TAG salts is dissociation to TAG and an associated product from the anion. The observed onset temperature for decomposition was between 383 and 393 K (110 and 120 °C) for TAGzT and TAGN, and 438 K (165 °C) for TAG-TATTz.

Mixtures of 75, 50, 25, and 10% RDX with TAGzT were mixed with the non-solvent methanol, stirred, dried, and pressed into 6.6-mm pellets [344, 345]. TAGzT can significantly increase the burning rate of RDX in nitramine propellants. TAGzT and RDX have a synergistic interaction during combustion. A mixture of 10 RDX/90 TAGzT burned five times faster than pure RDX and about 1.2 times faster than pure TAGzT, while having a lower pressure sensitivity than that of both parent compounds. A graph showing the burning rate vs. pressure curve of TAGzT/RDX mixtures is shown in chapter “Heterocyclic and Heterocycloaliphatic Amines.”

TAGzT can significantly increase the burning rate of nitrate ester propellants [346].

The decomposition of TAGAT followed decomposition pathways with a decomposition mechanism entirely different from that of GAT [204]. The difference was attributed to the introduction of the triamino group. The TGA curve of TAGAT revealed a four-stage weight-loss process (Figure 35).

**Figure 35:** DTA (left) and TGA (right) thermograms of triaminoguanidinium azotetrazolate. (Republished and modified from [204], with permission of ©2009 American Institute of Aeronautics Astronautics; permission conveyed through Copyright Clearance Center Inc.)

The first stage corresponded to a rapid exothermic reaction simultaneously observed in the parallel DTA between 414 and 432 K (141 and 159 °C), resulting in an 8% weight loss; the second stage also corresponded to the rapid exothermic reaction between 446 and 456 K (173 and 183 °C), corresponding to a 26% weight loss; the third stage corresponded to the exothermic decomposition between 456 and 471 K (183 and 198 °C), corresponding to a 35% weight loss; and the fourth and final stage corresponded to a very slow endothermic reaction between 471 and 552 K (198 and 279 °C), corresponding to a 20% weight loss. The decomposition of TAGAT was initiated by the cleavage of the azo group rather than proton transfer initiation, as hypothesized in GAT.

Premature, slow reaction of TAGzT with other propellant ingredients such as RDX may limit the useful life of composite propellants containing TAGzT [347].

Density functional theory and volume-based thermodynamics calculations have been performed to study the crystal densities, heats of formation, energetic properties, and thermodynamics of formation for a series of ionic salts composed of triaminoguanidinium or ammonium cations and tetrazole-based anions [348]. Substitution with  $-\text{NF}_2$ ,  $-\text{CH}_2\text{NF}_2$ ,  $-\text{CF}_2\text{NF}_2$ , or  $-\text{C}(\text{NO}_2)_2\text{NF}_2$  groups on the tetrazole ring increased the densities of the salts. The densities of the tetrazole-based salts were affected not only by different substituents but also by different cations. The triaminoguanidinium cation is more effective than the ammonium cation for increasing the heats of formation of the tetrazolate salts.

Similar density functional theory calculations were performed for energetic nitrogen-rich salts composed of the triaminoguanidinium cation and 5-nitroiminotetrazolate-based anions [349].

#### 14.6.3 Other Triaminoguanidinium Salts with Heterocyclic Anions

Bis-(triaminoguanidinium) 3,3-dinitro-5,5-azo-1,2,4-triazolate (TAGDNAT) is a high-nitrogen-content molecule that derives its energy release from both a high heat of formation and intra-molecular oxidation reactions.

TAGDNAT shows promise as a propellant or explosive ingredient not only due to its high nitrogen content (66.35 mass-% N) but also due to its high hydrogen content

(4.34 mass-% H). Strand burning rate studies showed that TAGDNAT had one of the fastest low-pressure burning rates (at 6.9 MPa) measured to date, i.e., 6.79 cm/s at 6.9 MPa (39% faster than bis-triaminoguanidinium azotetrazolate [TAGzT], a comparable high-nitrogen/high-hydrogen material) [350]. Furthermore, its pressure sensitivity coefficient was 0.507, a 33% reduction compared to TAGzT.

5,5'-Diamino-3,3'-azo-1*H*-1,2,4-triazole can be made by reaction of 5-acetyl-amino-3-amino-1*H*-1,2,4-triazole with potassium permanganate. Protection of one amino group in 3,5-diamino-1*H*-1,2,4-triazole by acetylation allows selective reactions of the remaining free amino group to form the azo functionality. Reactions of 5,5'-dinitrimino-3,3'-azo-1*H*-1,2,4-triazole with inorganic and organic bases (ammonia, hydrazine, guanidine, aminoguanidine, triaminoguanidine) formed the corresponding nitrogen-rich triazolate salts, which were characterized by IR, Raman, and multi-nuclear NMR spectroscopy, MS, DSC, and XRD [351].

Density functional theory (DFT) and volume-based thermodynamics calculations were performed to study the crystal densities, heats of formation, and energetic properties of a series of ionic salts composed of triaminoguanidinium or ammonium cations and tetrazole-based anions [348]. Substitution of the tetrazole ring with  $-\text{NF}_2$ ,  $-\text{CH}_2\text{NF}_2$ ,  $-\text{CF}_2\text{NF}_2$ , or  $-\text{C}(\text{NO}_2)_2\text{NF}_2$  groups increased the densities of the salts. The densities of the tetrazolate-based salts were affected not only by different substituents but also by different cations. The  $-\text{CN}$  or  $-\text{N}_3$  groups were effective substituents for increasing the HOFs of the salts. The triaminoguanidinium cation is more effective than the ammonium cation for increasing the HOF of the tetrazole-based salts. Substitution of hydrogens with  $-\text{NO}_2$ ,  $-\text{NF}_2$ , or  $-\text{C}(\text{NO}_2)_2\text{NF}_2$  groups enhanced the predicted explosive performance of the salts. A study of the thermodynamics of formation of the salts revealed that all of the tetrazole-based salts with the triaminoguanidinium or ammonium cation could be synthesized using the proposed reactions.

Density functional theory and volume-based thermodynamics calculations were performed to study the effects of different substituents and linkages on the densities, heats of formation, energetic properties, and thermodynamics of a series of energetic nitrogen-rich salts composed of triaminoguanidinium cation and 5-nitroiminotetrazolate anions [349]. The results showed that the  $-\text{NO}_2$ ,  $-\text{NF}_2$  or  $-\text{N}_3$  group are effective substituents for increasing the densities of the 5-nitroiminotetrazolate salts, whereas the effects of the bridge groups on the density are coupled to those of the substituents. The substitution by  $-\text{NH}_2$ ,  $-\text{NO}_2$ ,  $-\text{NF}_2$ ,  $-\text{N}_3$ , or the nitrogen bridge is helpful for increasing the enthalpies of formation of these salts.

Triaminoguanidine also forms a salt with *N*-nitro-1*H*-tetrazol-5-amine:  $\text{CH}_9\text{N}_6 \bullet \text{CH}_3\text{N}_6\text{O}_2$ , CAS RN [1660-26-0].

Several high-nitrogen energetic materials based on the TAG ion with astonishing thermal behaviors and performances were synthesized by different metathesis reactions [352, 353]. Particularly the new compound triaminoguanidinium 1-methyl-5-ni-

triminotetrazolate (TAG-1 Me-AtNO<sub>2</sub>, TAG-MNT) showed powerful explosion performance and may be an alternative to RDX.

Triaminoguanidinium 1-methyl-5-nitriminotetrazolate

The structural and chemical properties of triaminoguanidinium 1-methyl-5-nitriminotetrazolate have been investigated at atmospheric pressure and under high-pressure isothermal compression using powder XRD, Raman, and IR spectroscopy [354, 355]. Beyond 15 GPa, pressure induces irreversible chemical reactions, culminating in the formation of a polymeric phase by 60 GPa.

The toxicity of triaminoguanidinium 1-methyl-5-nitriminotetrazolate (TAG-MNT) was evaluated in animal tests and *in vitro* assays [356]. In rats, TAG-MNT had no apparent adverse effect up to the limit dose of 2 g/kg. In the Ames assay, TAG-MNT was a weak mutagen only at the limit concentration of 2 g/L. TAG-MNT was not acutely toxic at the limit dose when administered to rats, but 14 d of daily oral exposure caused liver toxicity and death [357].

High-nitrogen compounds like TAG-MNT have the potential to stimulate algal growth at low concentrations in N-limited systems, like any good fertilizer would [358].

Triaminoguanidinium 3,3'-bis-1,2,4-oxadiazol-5-onate (TAG2-OD) with an N-content of 60% and a relatively low isobaric (20 bar) combustion temperature of 1420 K may be used in reduced-erosion gun propellants.

Triaminoguanidinium 3,3'-bis-1,2,4-oxadiazol-5-onate

The properties of these two compounds and several dinitramide salts are listed in Table 29 in comparison to the properties of RDX.

Aminoguanidinium, diaminoguanidinium, triaminoguanidinium, and aminonitroguanidinium salts of cyanuric acid are thermally stable, high-nitrogen compounds [359].

**Table 29:** Properties of TAG-based energetic compounds.

| Property                                                   | Units             | RDX (for comparison) | TAG 1-MeAtNO <sub>2</sub> | TAG OD | AF_DN <sup>a</sup> | TAG_DN | HAT_DN |
|------------------------------------------------------------|-------------------|----------------------|---------------------------|--------|--------------------|--------|--------|

<sup>a</sup> Monohydrate

Abbreviation legend: triaminoguanidinium 1-methyl-5-nitriminetetrazolate = TAG 1-MeAtNO<sub>2</sub>; triaminoguanidinium 3,3'-bis-1,2,4-oxadiazol-5-onate = TAG OD; azidoformamidinium dinitramide = AF\_DN; 1,3,5-triaminoguanidinium dinitramide = TAG\_DN, 5-aminotetrazolium dinitramide = HAT\_DN

Data source: [352]

High-nitrogen-content energetic salts of ammonium, hydrazinium, guanidinium, aminoguanidinium, diamino-guanidinium, and triaminoguanidinium with 5-nitro-2*H*-tetrazolate anions were synthesized [360].

#### 14.6.4 Triaminoguanidinium Cyanoformate

Another high-nitrogen compound, triaminoguanidinium cyanoformate, C<sub>5</sub>H<sub>9</sub>N<sub>9</sub>, [(NH<sub>2</sub>NH)<sub>3</sub>C]<sup>+</sup> [C(CN)<sub>3</sub>]<sup>–</sup>, can be obtained from triaminoguanidinium sulfate and potassium cyanoformate in sulfuric acid solution [361].

Triaminoguanidinium dicyanamidate, C<sub>3</sub>H<sub>9</sub>N<sub>9</sub>, [(NH<sub>2</sub>NH)<sub>3</sub>C]<sup>+</sup> [N(CN)<sub>2</sub>]<sup>–</sup>, can be prepared by reaction of triaminoguanidinium sulfate with calcium cyanamidate, where the insoluble calcium sulfate precipitates and can easily be separated from the reaction mixture [362]. It melts at 396–397 K (123–124 °C), has a density of 1.415 g/cm<sup>3</sup> at 298 K and an enthalpy of formation of +400 ± 7 kJ/mol (+95.5 ± 1.8 kcal/mol), and

is non-hygroscopic. In the DTA it shows a sharp endotherm at 396 K = 123 °C (melting) and an exotherm at 423 K (150 °C).

#### 14.6.5 Bis-Triaminoguanidinium Decahydrodecaborate

Normally, nitrogen in energetic compounds converts to dinitrogen in the exhaust and does not contribute much to energy release. If the high-nitrogen compound is combined with a boron compound, the boron nitride formed in the exhaust contributes substantially to the overall energy release. One of the compounds in this category is bis-triaminoguanidinium decahydrodecaborate,  $[(\text{NHNH}_2)_3\text{C}]_2\text{B}_{10}\text{H}_{10}$  [363, 364].

#### 14.6.6 Triaminoguanidinium *N,N'*-Dinitro-1,2-Ethanediamine Salt

The salt formed from triaminoguanidine with *N,N'*-dinitro-1,2-ethanediamine,  $[(\text{NH}_2\text{NH})_3\text{C}]^+[\text{O}_2\text{NNHCH}_2\text{CH}_2\text{NNO}_2]^-$ ,  $\text{C}_3\text{H}_{14}\text{N}_{10}\text{O}_4$ , melts at 464–466 K (191–193 °C), and the maximum of the exotherm peak in the DTA is at 488 K (215 °C) [172].

#### 14.6.7 Other Triaminoguanidinium Salts

Triaminoguanidinium phosphate can be used to improve the performance and flammability characteristics of low-vulnerability propellants [365].

Polycondensation of triaminoguanidinium chloride with glyoxal results in a polymer (TAGP) which has a carbon-to-nitrogen ratio of 3:4, identical to the ratio found in carbon nitrides with a layered 2D network-type structure [366]. TAGP has a higher nitrogen content than all currently used energetic polymers, including glycidyl azide polymer (GAP); poly(3-nitrato-methyl-3-methyloxetane), poly-NIMMO; and poly(glycidyl nitrate), poly-GLYN. The properties of TAGP could be even further modified and tuned by coordination of transition metal ions.

## 15 Nitroguanidine and Dinitroguanidine

Nitroguanidine, also known as  $\text{CH}_4\text{N}_4\text{O}_2$ ,  $\text{C}_1\text{H}_4\text{N}_4\text{O}_2$ , NQ, NGu, NIGU, "picrite", CAS-RN [556-88-7], is prepared by dehydration of guanidinium nitrate by treating it with concentrated sulfuric acid. Nitroguanidine crystallizes in white, fiber-like crystals. Nitroguanidine is a very versatile energetic material additive for explosives, propellants, and gas generants. In gun propellants, it is the addition of NQ to reduce flame temperature and barrel wear that makes a triple-base propellant out of a double-base propellant. Nitroguanidine is a nitramine and should have been discussed in chapter "Nitramines" along with other nitramines, but somehow it was kept here with its parent imide, guanidine. The same rationale was applied for dinitroguanidine and nitroaminoguanidine, which are also discussed here in the following sections instead of in the "Nitramines" chapter.

Ordinarily, the abbreviation for **nitroguanidine** would be NG, but because NG was already in use as an abbreviation for **nitroglycerin**, the alternate acronym of NQ became generally accepted in the explosives lingo.

The structure commonly accepted for nitroguanidine was structure (II) shown below,

but other observations indicated a nitrimine structure (III) or even a partial zwitterion structure (IV)  $\leftrightarrow$  (V)

where the positive charge is not localized but can oscillate among the nitrogen atoms [367].

### 15.1 Production of Nitroguanidine

Nitroguanidine can be prepared from guanidinium nitrate, which is dehydrated by treatment with concentrated sulfuric acid.

Another method for preparation of NQ is by fusing urea with ammonium nitrate and then recrystallizing the product from boiling water (92% yield)

Another method is by enclosing an equimolar aqueous solution of cyanamide and ammonium nitrate in an autoclave, heating to 433 K (160 °C) under pressure (1.379 MPa = 200 psia), and recrystallizing the product from boiling water (88% yield)

## 15.2 Physical Properties of Nitroguanidine

Nitroguanidine is usually used as a component in mixed explosives and propellants. It has two crystal structures, namely  $\alpha$  and  $\beta$ , the former being more stable than the latter. The crystals are white needles that are neither hygroscopic nor volatilize at room temperature. The physical properties of NQ are summarized in Table 30. NQ is insoluble in cold water and diethyl ether, only somewhat soluble in ethanol, but soluble in aqueous alkaline solutions.

**Table 30:** Physical properties of nitroguanidine.

| Property                             | SI units                | Other units               | At temp. | References      |

| Heat of sublimation                  | 142.7 ± 2.0 kJ/mol      | 34.1 ± 0.5 kcal/mol       |          | [105]           |
| Oxygen balance (to CO <sub>2</sub> ) | −30.8%                  |                           |          |                 |

An older publication listed an NQ melting point of 329–331 K (56–58 °C), but that is most likely a mistake [172]. Additional information on the properties of nitroguanidine can be found in [372].

### 15.2.1 Mechanical Physical Properties of Nitroguanidine

Melting points of a eutectic mixture of hydrazinium(1+) nitrate (HN) and nitroguanidine (NQ) as well as fusion enthalpy of the pure components and the eutectic were determined using DSC [373]. The structure of the HN-NQ eutectic was characterized by IR, XRD, and SEM. Thermodynamic functions such as excess Gibb's energy, excess enthalpy, and excess entropy of the HN-NQ eutectic were calculated using activity coefficient data. The inter-molecular interactions of different molar ratios of the HN-NQ eutectic were determined by density functional theory (DFT) methods. The results of the excess thermodynamic functions and computer simulations indicated that the eutectic is not a mechanical mixture. IR spectroscopic and XRD studies confirmed that there is some interaction between the components during the formation of the eutectic mixture. In particular, the microstructure of the eutectic mixture at a molar ratio of 3 : 2 was more uniform than others. Similar eutectics were formed with methyl-nitroguanidine and hydrazinium(1+) nitrate [374].

A study of eutectic and peritectic points in the binary systems HN/nitroguanidine (HN/NQ) and HN/methylnitroguanidine (HN/MeNQ) detected indications of double salt formation with a well-defined stoichiometric ratio. The HN/NQ binary system showed the presence of a new substance, which is probably a HN/NQ co-crystal. No new substance was detected in the MeNQ/HN binary system [375]. The HN/NQ system had two eutectics, one at an NQ mol fraction of 0.226, melting at 322 K (49 °C), and another at a mol fraction of 0.95, melting at 416 K (143 °C). In between was a peritectic melting at 500 K (227 °C), with a composition of three mols of NQ per mol HN. The HN/MeNQ had only one eutectic at a MeNQ mol fraction of 0.307 melting at 341.7 K (68.6 °C).

### 15.2.2 Optical Properties of Nitroguanidine

#### 15.2.2.1 Infrared Spectra of Nitroguanidine

The IR spectrum of nitroguanidine is shown in Figure 36 (from [21]). Unfortunately, most IR spectra of NQ found in the literature were of poor quality, which is surprising considering that this is an important chemical for formulating explosives and propellants. Many of the spectra were taken with the samples dispersed in nujol mulls, and the absorption of the dispersing fluid interfered with clean spectra.

An examination of the spectra of nitroguanidine (Figure 37), nitroaminoguanidine, and guanidinium nitrate showed that the region from 7.5 to 15  $\mu\text{m}$  was barren of any large peaks, except in the case of guanidinium nitrate, where the nitrate ion manifests at 12.1  $\mu\text{m}$ . The other nitrate salts also gave this band. However, mono-, di-, and triaminoguanidine in the form of their nitrate salts have absorption peaks at 10.35 and 13.0  $\mu\text{m}$ . These bands correspond to two of the strong bands in the hydrazinium(1+) chloride spectrum and can be attributed to the hydrazine-type NH—NH linkage. In

**Figure 36:** Infrared spectrum of nitroguanidine. (Reproduced and modified from [21].)

**Figure 37:** Infrared spectrum of nitroguanidine. (Reproduced and modified from [125], with permission from Levering Estate.)

Figure 37, absorption in the area with the dashed lines is due to the solvent in which the crystals were suspended. IR absorption bands in the IR spectrum of NQ were assigned as follows [376]:

|         |                    |
|---------|--------------------|
| 2.96 μm | N—H                |
| 3.01 μm | N—H                |
| 3.13 μm | N—H                |
| 3.20 μm | N—H                |
| 6.01 μm | C=N                |
| 6.11 μm | —NO <sub>2</sub> . |

In the C—H first combination region, the N—H first combination region (2300–1900 nm) of NQ was extraordinarily complex and the particular assignment of each band to the respective N—H stretching/bending combination mode was not feasible [377]. As a general assignment, the bands located at 1973, 2007, 2036, and 2083 nm were tentatively assigned to a combination of N—H stretching with N—H bending vibrations ( $\nu\text{NH} + \delta\text{NH}$ ), based on the available literature reported for amines. The bands above 2100 nm (2174, 2221, and 2262 nm) might be due to second overtones of N—H bending vibrations ( $3\delta\text{NH}$ ) and the combination of N—H stretching with N—N stretching/bending vibrations ( $\nu\text{NH} + \nu\text{NN}/\nu\text{NH} + \delta\text{NN}$ ).

Another IR spectrum of NQ found in the literature has been spliced together from several spectra of NQ suspended in different solvents, appears to be incomplete, and is not very useful [76] (Figure 38).

**Figure 38:** Infrared spectrum of nitroguanidine. (Reproduced and modified from [76].)

#### 15.2.2.2 Raman Spectra of Nitroguanidine

Fourier transform Raman (FTR) spectroscopy employing near-IR laser radiation at 1.06  $\mu\text{m}$  as the scattering source has been used to obtain Raman spectra of NQ and propellant formulations containing NQ [378, 379] (Figure 39).

#### 15.2.2.3 Ultraviolet Spectra of Nitroguanidine

The UV spectrum of a nitroguanidine solution in ethanol shows an absorption peak at 265 nm (Figure 40).

**Figure 39:** Raman spectrum of nitroguanidine. (Reproduced and modified from [378].)

**Figure 40:** Ultraviolet spectrum of nitroguanidine. (Reproduced and modified from [76].)

### 15.2.3 Thermodynamic Properties of Nitroguanidine

The molar heat capacity of NQ in the range 200–460 K (–73 to +187 °C) can be described by the following linear equation

$$C_p = (6 \pm 1) + (0.08 \pm 0.003)T$$

where  $C_p$  is the molar heat capacity in  $\text{cal mol}^{-1} \text{°C}^{-1}$  and  $T$  is the temperature in kelvin [371]. The molar heat capacity of NQ at 298 K is  $129.3 \text{ J mol}^{-1} \text{K}^{-1}$  ( $30.9 \text{ cal mol}^{-1} \text{°C}^{-1}$ ).

Energies of combustion of guanidine, nitroguanidine, and four nitroguanidine derivatives were measured by combustion calorimetry, and their enthalpies of formation were calculated and compared [380] (Table 31). A study of the influence of the effective energy of non-valency interactions of functional groups (EEI) on thermochemical properties of nitro derivatives of the guanidine will enable enthalpies of formation to be predicted just by looking at the structural formula of nitramines in the future.

**Table 31:** Thermochemical properties of guanidine, nitroguanidine, and derivatives of nitroguanidine.

| Compound                                                                                | Upper heat of combustion |                 | Standard enthalpy of formation |                 |
|-----------------------------------------------------------------------------------------|--------------------------|-----------------|--------------------------------|-----------------|
|                                                                                         | kJ/mol                   | kcal/mol        | kJ/mol                         | kcal/mol        |

Data source: [380]

The heat capacity of NQ with a density of  $1.689 \text{ g/cm}^3$  in the range 310–440 K (37–167 °C) was

$$c_p = 0.269 + 0.00070t$$

where  $c_p$  is the heat capacity in  $\text{cal g}^{-1} \text{ °C}^{-1}$  and  $t$  is the temperature in °C [381]. The mid-range standard deviation was  $0.006 \text{ cal g}^{-1} \text{ °C}^{-1}$ . The thermal conductivity of the same sample of NQ at 314 K (41 °C) measured by a DSC comparative method was as follows:

$$\lambda = 9.85 \times 10^{-4} \text{ cal cm}^{-2} \text{ °C}^{-1} \left( \frac{\text{°C}}{\text{cm}} \right)^{-1} = 0.412 \text{ W m}^{-1} \text{ K}^{-1}$$

No complete vibrational assignments for NQ were available and, therefore, its thermodynamic functions in the vapor state could not be calculated by the statistical thermodynamic method. There are no experimental data on the enthalpy of formation of gaseous NQ. The calculated enthalpy of formation for NQ in the gas phase is  $-1 \pm 20 \text{ kJ/mol}$  and the calculated entropy is  $352 \pm 5 \text{ J mol}^{-1} \text{ K}^{-1}$  [382].

#### 15.2.4 Molecular Structure of Nitroguanidine

The nitrimine structure

has been established for NQ  $(\text{NH}_2)_2\text{C}=\text{N}-\text{NO}_2$  by XRD [383], neutron diffraction [384], spectroscopic measurements [385], and theoretical investigations [386].

Crystalline nitroguanidine exists in at least two crystal modifications,  $\alpha$ -nitroguanidine and  $\beta$ -nitroguanidine. The  $\alpha$ -form may be prepared by dissolving guanidinium nitrate in concentrated sulfuric acid and drowning the solution with water. It crystallized from hot water in long, flexible needles, which are mechanically strong and difficult to pulverize. The  $\beta$ -nitroguanidine can be prepared by nitrating a mixture of guanidinium sulfate and ammonium sulfate. It crystallized from hot water in fern-shaped clusters of small, thin, elongated plates. The  $\beta$ -form can be converted to the  $\alpha$ -form by dissolving in concentrated sulfuric acid and drowning it with lots of water.

The two modifications of NQ have the same melting point, but their solubility in water differs somewhat except at 298 and 373 K (25 and 100 °C), where the solubilities are identical. Between 298 and 373 K (25 and 100 °C), the solubility is slightly lower for the  $\alpha$ -form.

$^{15}\text{N}$ ,  $^1\text{H}$ , and  $^{13}\text{C}$  NMR spectroscopy spectra confirmed the nitroimine structure which had been suggested by other investigations in recent years and did not lend

any support to the commonly used nitroamine structure or to a tautomeric equilibrium with the nitroamine [387]. The  $^{15}\text{N}$  spin coupling constants to the neighboring  $^1\text{H}$  and  $^{13}\text{C}$  nuclei in the assigned structure confirmed this conclusion.

An investigation of the tautomeric properties of NQ using theoretical approaches for NQ in both the gas phase and in aqueous solution used a density functional method to estimate physical and chemical properties of NQ tautomers [388]. In order to analyze NQ behavior in aqueous solution, several properties were calculated. Deprotonating as well as protonating of NQ revealed positive energies, indicating that those processes are rather unfavorable and further characterized NQ as a compound with weak acid–base properties.

### 15.3 Chemical Properties of Nitroguanidine

Nitroguanidine is a powerful explosive, but its oxygen balance is still on the negative side with  $-30.7\%$ . It has excellent chemical stability. Nitroguanidine is soluble in hot water but practically insoluble in cold water. It is only very sparingly soluble in alcohol, insoluble in ether, but readily soluble in aqueous alkaline solutions.

Nitroguanidine derivatives, including *N*-methyl-*N'*-nitroguanidine (MeNQ), 3-amino-1-nitroguanidine (ANG), hydrazobis(nitroformamidine) (HABNF) 1-(2,2,2-trinitroethylamino)-2-nitroguanidine (TNEANG), 3,5-diamino-1-nitroamidino-1,2,4-triazole (DANAT), 2-nitroimino-5-nitrohexahydro-1,3,5-triazine (NNHT), and 1,2-dinitroguanidine (DNG) have been prepared in the hope of obtaining compounds with properties superior to those of NQ [389].

Reactions between *N*-nitroso-*N'*-alkylguanidines and the hydrazine derivatives of 1,3,5-triazine or 1,2,4,5-tetrazine resulted in a new class of nitroguanidyl-function-alized nitrogen-rich materials derived from 1,3,5-triazine and 1,2,4,5-tetrazine [390]. These compounds were characterized using NMR, IR, DSC, and elemental analysis, and detonation pressures and velocities were predicted from theoretical calculations.

#### 15.3.1 Reactions of Nitroguanidine

Nitroguanidine undergoes hydrazinolysis when reacted with hydrazine hydrate in a 1 : 1 molar ratio to form nitraminoguanidine, which is also an explosive and intermediate in the synthesis of other energetic compounds. Reaction of nitraminoguanidine with potassium nitrite in the presence of acetic acid gives the potassium salt of 5-nitraminotetrazole.

##### 15.3.1.1 Nitroguanidinium Salts

Nitroguanidine forms a monoperchlorate salt (NGP) and a diperchlorate salt with perchloric acid. Nitroguanidinium monoperchlorate forms when dissolving NQ in anhydrous perchloric acid. The diperchlorate forms from the monoperchlorate with even

more perchloric acid. The monoperoxchlorate salt melts and decomposes in reversal of its formation at 393 K (120 °C). The diperoxchlorate salt melts at 343 K (70 °C) and explodes at 366 K (93 °C). NGP has been reported to be less stable than GP.

The first step of the thermal decomposition of NGP begins in the solid phase and proceeds as follows, with guanidinium perchlorate as an intermediate product [115]:

Nitroguanidine is amphoteric and forms salts with strong alkalis as well as with strong acids. Nitroguanidinium nitrate forms by dissolving NQ in hot, concentrated nitric acid and allowing to cool, forming rhombohedral crystals. The crystals melt at 420 K (147 °C) under decomposition. The crystals are very sensitive to impact and will explode. The crystals lose nitric acid when standing in air at room temperature. Crystal structures of nitroguanidinium chloride and nitroguanidinium nitrate were examined by XRD [391]. The nitroguanidinium chloride crystal is triclinic, space group *P*1, with unit cell parameters  $a = 6.656(8) \text{ \AA}$ ,  $b = 6.719(9) \text{ \AA}$ ,  $c = 6.816(8) \text{ \AA}$ ,  $\alpha = 66.8(2)^\circ$ ,  $\beta = 75.4(2)^\circ$ ,  $\gamma = 84.5(2)^\circ$ ,  $DC = 1.7 \text{ g/cm}^3$ ,  $Z = 2$ . The nitroguanidine nitrate crystal is monoclinic, space group *P*2<sub>1</sub>/*c* with unit cell parameters  $a = 4.587(4) \text{ \AA}$ ,  $b = 6.377(6) \text{ \AA}$ ,  $c = 21.167(15) \text{ \AA}$ ,  $\beta = 94.7(1)^\circ$ ,  $DC = 1.8 \text{ g/cm}^3$ ,  $Z = 4$ .

#### 15.3.1.2 Nitroguanidinate Salts

It is the general format of this book that salts are primarily listed under their cation and not under their anion. Thus there are several nitroguanidinate salts listed in other sections of this book, e.g., in chapter “Heterocyclic and Heterocycloaliphatic Amines.”

#### 15.3.2 Decomposition of Nitroguanidine

In the vacuum stability test at 373 K (100 °C), the gas evolved by a one-gram sample of NQ in 48 h was 0.37 cm<sup>3</sup>. The investigations of the decomposition of NQ have been performed mostly at temperatures between 463 and 513 K (190 and 240 °C). The aim of additional work was to study the decomposition behavior of NQ at temperatures as low as possible, namely at temperatures between 383 and 513 K (110 and 240 °C) [392]. In this temperature range, NQ with different grain sizes has been investigated by measuring the weight loss and analyzing the decomposition gases by MS. Solid residues, such as ammeline and melamine, remaining after the degradation tests were analyzed quantitatively by HPLC. The formation of melamine and ammeline was found to depend strongly on the extent of the weight loss of NQ. The better stability behavior of triple-base propellants in the presence of NQ is possibly due to the presence of NH<sub>3</sub>, which is formed in the decomposition of NQ. Ammonia reacts with and sequesters nitric oxides, and therefore acts similarly to a stabilizer. In the DTA, the maximum of exothermic decomposition of NQ was at 523 K (250 °C) [172].

The off-gassing of NQ decomposition products measured with a thermoconductivity GC detector (--- dashed line) was superimposed on the DTA trace (— solid line)

of NQ as shown in Figure 41 [393]. The off-gassing started simultaneously with the exotherm. The exotherm started before the melting. The melting endotherm is superimposed on the exotherm at ~500 K (~230 °C).

**Figure 41:** Off-gassing of NQ during decomposition superimposed on the DTA trace of NQ. (Reproduced and modified from [393].)

### 15.3.3 Specifications for Nitroguanidine

The procurement of NQ is governed by MIL SPEC MIL-N-494A (Mar 1963) superseding JAN-N-494 of Sep 1947, amended 11 Apr 1983 and 8 Aug 2013. The MIL SPEC contains several analysis methods for NQ.

## 15.4 Safety Properties of Nitroguanidine

Nitroguanidine is not very sensitive to shock or impact. In the USBM impact tester with the No. 12 tool and a 5-kg weight, the tests were negative at the maximum range of the machine (177 cm) [393].

### 15.4.1 Shock Sensitivity of Nitroguanidine

When testing the impact sensitivity at impact energies up to  $5 \text{ kJ} = 49 \text{ N m}$  there was no reaction. Impact sensitivity when measured in the Bureau of Mines Apparatus with a 2-kg mass was 47 cm, which was more sensitive than either TNT or PA. In the Picatinny Arsenal Apparatus with a 1-lb mass, the drop-weight sensitivity was 66 cm (26 in.).

In the NOL Large Scale Card-Gap Test, finely ground NQ at three different packing densities, 1.39, 1.44, or  $1.50 \text{ g/cm}^3$ , had card-gap sensitivities (50% positive) of 109, 98, or 81 cards, corresponding to attenuated shock pressures of 52, 56, or 63 kbar [394].

### 15.4.2 Friction Sensitivity of Nitroguanidine

When testing the friction sensitivity of NQ at pistil loads up to  $36 \text{ kp} = 353 \text{ N}$  there was no reaction.

### 15.4.3 Critical Diameter of Nitroguanidine Detonations

In studying the explosive behavior of NQ, a high-bulk density (NQ-h) and a low-bulk density (NQ-l) form of this material were examined [395]. Determination of failure limits in the charge diameter–density ( $\rho_0$ ) plane showed that both behave as a group 1 explosive (critical diameter decreasing with  $\rho_0$  increasing) at  $\rho_0 < 1.63 \text{ g/cm}^3$ , but that NQ-h exhibited “dead-pressing” and, thus, behaved as a group 2 explosive at higher densities. NQ-h had a large critical diameter, about three times that of NQ-l, in the range of their detonability.

## 15.5 Toxicity of Nitroguanidine

The toxicity of NQ was thoroughly re-examined in the late 1980s in parallel with measuring the toxicity of GuN from which it is made. However, only few military and contractor personnel ever get exposed to GuN, whereas exposure to NQ at LAP operations and in the field and during demilitarization operations is more likely. Consequently, a wider range of toxicity test protocols were applied to NQ than to GuN and performed in parallel [396].

### 15.5.1 Oral Toxicity of Nitroguanidine

Nitroguanidine was administered to rats in the diet at dose levels of 0, 100, 316, and 1000 mg kg<sup>-1</sup> d<sup>-1</sup> for 14 d [397]. The addition of NQ to the diet did not have an effect on food consumption, but there was a significant dose-response increase in water consumption. There were no observable clinical signs attributable to the NQ feeding. Microscopic examination of tissues from the control and 1000 mg kg<sup>-1</sup> d<sup>-1</sup> dose group animals revealed no lesions attributable to the administration of NQ. These findings indicated that NQ is non-toxic in rats when administered at doses as high as 1000 mg kg<sup>-1</sup> d<sup>-1</sup> for 14 d. Nitroguanidine is excreted unchanged in the rats' urine and may act as an osmotic diuretic. Essentially identical results were obtained in a 90-d feeding study using mice instead of rats [398].

The median lethal dose of NQ is greater than 5000 mg/kg body weight in both male and female rats [399, 400] or mice [401]. The predominant clinical signs associated with nitroguanidine administration were urinary excretion of a whitish precipitate (nitroguanidine) in the first 24 hours followed by excretion of a reddish urine for up to a week. Chemical analyses of a whitish crystalline material isolated from the urinary bladder of a rat indicated that the crystalline material was nitroguanidine.

The acute oral toxicity of NQ in mice was at or above the limit value of 5000 mg/kg which produced less than 50% mortality in male mice, while in female mice, the median lethal dose was 4345 mg/kg [402]. Similar toxicity tests were conducted with nitrosoguanidine, which is not used as a propellant or explosive, but may co-exist as a contaminant or degradation product of NQ.

### 15.5.2 Dermal Toxicity of Nitroguanidine

The dermal sensitization potential of nitroguanidine was tested in guinea pigs [403, 404] and rabbits [405, 406]. There was very little skin irritation.

### 15.5.3 Mutagenicity of Nitroguanidine

Nitroguanidine was not mutagenic under the conditions of the mouse lymphoma thymidine kinase forward-mutation assay either with or without prior metabolic activation by rat liver at concentrations ranging from 0.01 to 4 mg/mL [407]. Nitroguanidine was not mutagenic under conditions of the Ames *Salmonella*/mammalian microsome mutagenicity test at doses ranging from 2.8 to 0.0875 mg/plate [408]. Nitroguanidine was non-mutagenic in the *Drosophila melanogaster* sex-linked recessive lethal test following 72-h feeding exposures to concentrations of NQ ranging from 2.08 to 20.8 µg/mL [409].

The potential of NQ to induce sister-chromatid exchanges (SCEs) was assessed using Chinese hamster ovary cells both with and without exogenous metabolic acti-

vation achieved by addition of rat liver extract [410]. Nitroguanidine at concentrations of 4 to 0.01 mg/mL did not induce a statistically significant increase in SCEs either with or without exogenous metabolic activation.

#### 15.5.4 Teratogenicity of Nitroguanidine

Teratogenicity of NQ was evaluated by feeding NQ suspended in 1% carboxymethyl-cellulose at doses of 0, 100, 316, or 1000 mg kg<sup>-1</sup> d<sup>-1</sup> on days 6 through 15 of gestation to pregnant rats [411]. Fetuses were delivered by cesarean section on day 20, weighed, and examined externally. Fetuses from the 1000 mg kg<sup>-1</sup> d<sup>-1</sup> group were significantly smaller than controls with an increased incidence of retarded ossification of the sternbrae, caudal vertebrae, and pubis. Nitroguanidine caused maternal and fetal toxicity at the 1000 mg kg<sup>-1</sup> d<sup>-1</sup> dose level. The no-observed-effect level was 316 mg kg<sup>-1</sup> d<sup>-1</sup>.

In similar tests with rabbits instead of rats [412], fetuses in the 1000 mg kg<sup>-1</sup> d<sup>-1</sup> group were lighter in weight and had an increased incidence of retarded ossification of the sternbrae, olecranon, patellae, and phalanges. There were no dose-related malformations. It was concluded that NQ had no teratogenic potential but does have the potential to cause developmental toxicity.

In a three-generation study with rats, there were no dose-related effects on clinical signs, mating, fertility, gestation, litter size, pup weight, or survival [413]. Histopathological examination of the reproductive organs in adult animals and gross examination of weanlings showed no lesions attributable to NQ in any of the generations.

#### 15.6 Explosive Performance of Nitroguanidine

The cavity enlargement in the lead block test (Trauzl test) was 305 cm<sup>3</sup>/10 g, which is not a very large value. The detonation velocity of NQ confined and pressed into a steel tube at maximum density is 8200 m/s = 26900 ft/s. Other sources give the detonation velocity as 5360 m/s at a packing density of 1.0 g/cm<sup>3</sup> and 7650 m/s at a packing density of 1.5 g/cm<sup>3</sup>. Other sources give the detonation velocity as 7700 m/s and the C-J pressure (measured) as 253 kbar at a packing density of 1.6 g/cm<sup>3</sup> [393].

#### 15.7 Applications of Nitroguanidine

Nitroguanidine can be incorporated into single-base, nitrocellulose powder, and glycerol trinitrate or diethylene glycol dinitrate gelatinized double-base propellants. In these mixtures, it is not dissolved in the powder gel, but is embedded in it as a fine

dispersion. These “cold” (calorie-poor) powders erode gun barrels at a much slower rate than do the conventional “hot” powders. In addition, nitroguanidine has the advantage of quenching muzzle flash, but smoke formation is somewhat more intensive. NQ-NC gun propellants were already in use during World War II.

#### 15.7.1 Demilitarization and Recycling of Nitroguanidine

Laboratory-scale solubility and extraction studies were carried out to investigate the feasibility of recovery of NQ from M30 triple-base gun propellant [414]. The recovery process involved stripping nitroglycerine (NG) from M30 propellant using supercritical carbon dioxide, followed by aqueous extraction of NQ. The solubilities of NQ and NG in supercritical CO<sub>2</sub> were investigated. NQ was found to be relatively insoluble. NG was found to be up to six orders of magnitude more soluble than NQ in supercritical CO<sub>2</sub>. The solubility of NQ in water from 301 to 348 K (28 to 75 °C) was measured at atmospheric pressure. The solubility data were found to follow an exponential function of  $1/T$  over a range of 273 to 373 K (0 to 100 °C). The solubility of NQ varied by almost two orders of magnitude over this temperature range. NQ was readily extracted from NG-depleted M30 propellant using hot water. The bulk of the NQ was recovered by precipitation at 272 K (1 °C). A small amount of NQ remained unrecovered in the extraction solution.

#### 15.7.2 Environmental Degradation of Nitroguanidine

Nitroguanidine spilled on the ground and soaking into soil will eventually disappear by biodegradation [314, 415].

The stability of NQ was evaluated in three moist unsaturated soils under laboratory conditions [416]. The three soils were fortified using an aqueous spiking solution and the residual concentration of NQ was measured after storage for 0, 1, 2, 4, and 8 d at 273 K (20 °C) in the dark. The results yielded a range of half-life decay estimates for nitroguanidine from 7.5 to 56 d, depending on the soil type. No attempt was made to determine environmental transformation products of NQ in the soil or leachate.

### 15.8 Alkyl-Nitroguanidines

1-Methyl-3-nitroguanidine, *N*-methyl-*N'*-nitroguanidine, C<sub>2</sub>H<sub>6</sub>N<sub>4</sub>O<sub>2</sub>, CAS RN [4245-76-5], can be prepared by heating nitroguanidine dissolved in water containing KOH to 313 K (40 °C) and adding methylammonium chloride gradually with stirring. This gave a viscous sludge, and some ammonia was evolved. The temperature was raised gradually to 332–334 K (59–61 °C) over a period of 8 min, and held there for 23 min while stirring the mixture. After the mixture was cooled to 279 K (6 °C), a white precipitate of methylnitroguanidine was filtered off, washed with cold water, and dried. The raw

product melted at 424–427 K (151–154 °C). Recrystallization first from hot water and then from ethanol gave the pure product with a melting point of 433 K (160 °C).

Methylnitroguanidine

The oxygen balance of methylnitroguanidine for combustion to CO<sub>2</sub> is –67.7%.

Methylnitroguanidine has been evaluated as an insensitive munitions explosive. Additional information on methylnitroguanidine can be found in [417].

Methylnitroguanidine forms a nitrate salt that melts at 360–364 K (87–91 °C) and a perchlorate salt that melts at 377 K (104 °C). The perchlorate was very sensitive to impact and detonated violently when hit with a hammer.

The melting point, crystal shape, structures, and interaction of different mixtures of 1-methyl-2-nitroguanidine and hydrazinium(1+) nitrate were tested by DSC, optical microscope, XRD, and density functional theory [374]. The experimental results showed that the lowest melting point was 340.2 K (67.06 °C); the most stable configuration, the needle-shape crystals, were different from methylnitroguanidine and hydrazinium nitrate, and appeared at a molar ratio of 3 : 2, and the structure was very uniform compared to other molar ratio eutectics. Quantum chemical calculation results showed that the eutectic is not a simply mechanical mixture but may be formed by some sort of loose molecular or atomic interaction, which may explain the observed enthalpy of fusion.

The crystal and molecular structure of *N*-methyl-*N'*-nitroguanidine, C<sub>2</sub>H<sub>6</sub>N<sub>4</sub>O<sub>2</sub>, molecular mass  $M = 118.096$  g/mol, have been determined by XRD at 115 K [418]. The space group is  $P2_1/n$ , with  $a = 4.6320$  Å,  $b = 10.1265(13)$ ,  $c = 11.2399(13)$  Å, and  $\beta = 100.164^\circ$ ,  $V = 518.94$  Å<sup>3</sup>,  $Z = 4$ , and  $\rho_{\text{calc}} = 1.511$  g/cm<sup>3</sup> at 115 K. The observed pycnometric density at 295 K was 1.50 g/cm<sup>3</sup>. The molecule is planar with an unusually long formal double C=N bond of 1.377 Å, and is interpreted as a zwitterionic structure.

1-Ethyl-2-nitroguanidine, C<sub>3</sub>H<sub>8</sub>N<sub>4</sub>O<sub>2</sub>,  $M = 132.13$  g/mol, is similar to other nitrimines [419]. The nitroguanyl group is planar and stabilized by an intra-molecular hydrogen bond. Inter-molecular hydrogen bonds hold the molecules together in the crystal. 1-Ethyl-2-nitroguanidine crystallized in transparent, colorless lumps, monoclinic crystals, space group  $P2_1/n$ , with the unit cell parameters of  $a = 8.9336(9)$  Å,  $b = 16.087(2)$  Å,  $c = 4.3173(4)$  Å,  $\beta = 96.119(8)^\circ$ ,  $V = 616.92(11)$  Å<sup>3</sup>,  $Z = 4$ ,  $\rho_{\text{XRD}} = 1.423$  g/cm<sup>3</sup> at  $T = 293$  K.

## 15.9 Dinitroguanidine

1,2-Dinitroguanidine,  $\text{CH}_3\text{N}_5\text{O}_4$ , DNQ, CAS RN [666736-83-0],

is a product of nitroguanidine nitration with nitric acid and its mixtures with sulfuric acid and oleum [420]. It melts at  $442\text{ K} = 169^\circ\text{C}$ . It is moderately soluble in water and organic solvents. It is a diacid ( $\text{p}K_{\text{a}}1.11$ ,  $\sim 11.5$ ) and at the same time a weak base, undergoing protonation at the nitrogen of the amino group ( $\text{p}K_{\text{b}}\text{H}^+ - 5.81$ ). The decomposition kinetics of 1,2-dinitroguanidine were studied by spectrophotometry in both acid and alkaline media. In the media of high acidity ( $\text{H}_0 > -8$ ), 1,2-dinitroguanidine underwent reversible denitration to nitroguanidine. At lower acidity its conjugate acid or molecular form underwent hydrolysis yielding nitrourea. The monoanion of 1,2-dinitroguanidine in a weak acid or, in alkali, was hydrolyzed into  $N,N'$ -dinitrourea. The reaction of 1,2-dinitroguanidine with alkali in alcohol yielded its salts, and with nitrogen-containing bases one can synthesize both salts and derivatives of 2-nitroguanidine. The synthesis, reactivity, and thermal characteristics of 1,2-dinitroguanidine were summarized in [421–423].

The molecular structure of dinitroguanidine is almost planar, and the conformation is fixed by two intra-molecular  $\text{N}-\text{H}\cdots\text{O}$  hydrogen bonds [424]. Due to the delocalization of  $\pi$ -electron density over the whole molecule, there is through-conjugation, with the  $\text{C}-\text{N}$ ,  $\text{N}-\text{N}$ , and  $\text{N}-\text{O}$  bond lengths having values intermediate between those typical for the corresponding single and double bonds. Methyl dinitroguanidine has a similar structure [425].

One of the salts described in the literature is the ammonium salt of dinitroguanidine [426, 427]. The salt crystallized in the monoclinic space group  $P2_1/c$  with a crystal density of  $\rho = 1.735\text{ g/cm}^3$ . The onset of exotherm during the decomposition of the ammonium salt of dinitroguanidine in a DSC is  $470\text{ K}$  ( $197^\circ\text{C}$ ), and its theoretical detonation velocity is  $9066\text{ m/s}$ , which somewhere between RDX and HMX. The impact sensitivity was  $10\text{ N}$ , and its friction sensitivity was  $252\text{ N}$ .

Nitrogen-rich salts of  $N,N'$ -dinitroguanidine, such as ammonium, hydrazinium, guanidinium, 1,3,5-triaminoguanidinium, urea, 5-aminotetrazolium, 1-methyl-5-aminotetrazolium, and 1,4-dimethyl-5-aminotetrazolium were synthesized by deprotonation or metathesis reactions and characterized by single-crystal XRD, IR and Raman spectroscopy, elemental analysis, and DSC [428]. The heats of formation were calculated as summarized in Table 32, along with density and thermal stability data. With these values and the experimental (X-ray) densities, predicted detonation

Table 32: Thermodynamic and thermal stability properties of dinitroguanidinate salts.

| Compound name                                      | Gross formula                                                 | Acronym                  | Density<br>g/cm <sup>3</sup> | $\Delta H_f^\circ(\text{S})$ |        | $\Delta n$ | $\Delta U_f^\circ(\text{S})$ |        | $\Delta U_c^\circ(\text{S})$ |     | Decomposition temp. |  |

Data source: [428]

parameters such as the detonation pressure, velocity, energy, and temperature were computed using the EXPLO5 code. The sensitivities towards impact, friction, and electrostatic discharge were tested using a BAM drop hammer, a friction sensitivity tester, and a small-scale ESD test device. Impact sensitivities ranged from 2 J for the hydrazinium salt to 40 J for the guanidinium and urea salts. Friction sensitivity ranged from 60 N for the ammonium and hydrazinium salts to 240 N for the guanidinium and urea salts.

The 4-amino-1,2,4-triazolium salt of dinitroguanidine was synthesized and characterized by XRD, TGA-DTG-DSC, and the Kamlet–Jacobs equation for crystal structure, thermal stability, and detonation properties [429]. The critical temperature of thermal explosion was 459 K (186 °C), the predicted detonation pressure was 29.8 GPa, and the predicted detonation velocity was 8.28 km/s. The impact sensitivity was  $h_{50} = 135$  cm.

Dinitroguanidine (DNG) was synthesized from nitroguanidine and 100% nitric acid/20% oleum/ammonium nitrate as a nitrating system [430]. The structure of DNG was identified by IR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, and MS. The thermal decomposition of DNG was studied using TGA and DSC. The peak temperature of the DSC thermogram for DNG was 456 K (183 °C), indicating that DNG has a very good thermal stability.

Dinitroguanidine has been extensively tested as an explosive [431, 432], and as a rocket propellant ingredient, replacing RDX or NQ [433]. The predicted detonation pressure and detonation velocity of DNG ranged from 24.8 to 30.3 GPa and 7665 to 8422 m/s, better than those of TNT [434].

The nitroguanyl azide, nitrocarbamidoyl azide,  $\text{CH}_2\text{N}_6\text{O}_2$ ,  $M = 130.09$  g/mol, crystal structure is stabilized by intra- and inter-molecular hydrogen bonds [435]. The molecule possesses a nitrimine structure.

Nitroguanyl azide

Nitroguanyl azide crystallized in colorless lumps, triclinic crystals, space group  $P\bar{1}$ , with the unit cell parameters of  $a = 9.9302(8)$  Å,  $b = 7.9433(9)$  Å,  $c = 7.1288(8)$  Å,  $\alpha = 98.31(1)^\circ$ ,  $\beta = 110.58(1)^\circ$ ,  $\gamma = 75.108(9)^\circ$ ,  $V = 507.83(9)$  Å<sup>3</sup>,  $Z = 4$ ,  $\rho_{\text{XRD}} = 1.701$  g/cm<sup>3</sup> at  $T = 293$  K.

## 16 Nitroaminoguanidine

Nitroaminoguanidine,  $\text{CH}_5\text{N}_5\text{O}_2$ , nitraminoguanidine, 1-amino-3-nitroguanidine; hydrazinecarboximidamide, *N*-nitro-; *N*-nitrohydrazinecarboximidamide, CAS RN [18264-75-0], can be obtained by reacting nitroguanidine with hydrazine hydrate in aqueous solution [436, 437].

The structure commonly accepted for nitroaminoguanidine was structure (II) shown above, but other observations indicate a nitrimine (III) or even a partial zwitterion structure,

where the positive charge is not localized but can oscillate among the nitrogen atoms [367].

The crystal structure of nitroaminoguanidine has been investigated by XRD [438]. XRD studies showed that nitroaminoguanidine crystals belong to the tetragonal system. The crystal structure parameters were  $a = 17.063 \pm 0.005 \text{ \AA}$ ,  $b = 17.063 \pm 0.005 \text{ \AA}$ ,  $c = 5.155 \pm 0.005 \text{ \AA}$  and  $c/a$  axial ratio = 0.302.

### 16.1 Physical Properties of Nitroaminoguanidine

Nitroaminoguanidine, 1-amino-2-nitroguanidine,  $\text{H}_2\text{N}-\text{NH}-\text{C}(=\text{NH})-\text{NH}-\text{NO}_2$ ,  $\text{CH}_5\text{N}_5\text{O}_2$ , CAS RN [18264-75-0], nitraminoguanidine, is an energetic compound that melts at 462 K (189 °C) and contains 58.8 mass-% nitrogen. Nitroaminoguanidine has an oxygen balance of -33.6%. The physical properties of nitroaminoguanidine are summarized in Table 33.

**Table 33:** Physical properties of nitroaminoguanidine.

| Property                                 | SI units                |               | Non-SI units              |             | Refer-<br>ences |

The IR spectrum of nitroaminoguanidine shows bands typical for C–NH and N–NO<sub>2</sub> bonds (Figure 42).

**Figure 42:** IR Spectrum of nitroaminoguanidine (Reproduced and modified from [125], with permission from Levering Estate.)

## 16.2 Chemical Properties of Nitroaminoguanidine

1-Amino-3-nitroguanidine (nitroaminoguanidine) can be synthesized by hydrazinolysis of nitroguanidine. Due to its amphoteric character, it can form stable salts with strong acids and strong bases. Salts of nitroaminoguanidine with oxidizing acids are powerful explosives and attractive high-nitrogen compounds which burn without leaving residues.

Study of the thermal decomposition of nitroaminoguanidine under temperature-programmed conditions in a DSC and isothermal conditions in a TGA showed that

under non-isothermal conditions, nitroaminoguanidine apparently decomposed in one stage, with a loss in weight of 80% [438]. But the slow thermal decomposition of nitroaminoguanidine in the solid phase under isothermal conditions proceeded via three stages. The first and the second stages obeyed the Avrami–Erofeev equation. Gaseous decomposition products detected using IR were  $\text{NH}_3$ ,  $\text{NO}_2$ ,  $\text{HCN}$ ,  $\text{N}_2\text{O}$ ,  $\text{CO}$ , and  $\text{CO}_2$ . High-temperature decomposition IR studies indicated preferential deamination reactions breaking the  $\text{N}-\text{NH}_2$  and  $\text{C}-\text{NH}_2$  bonds, leading to  $\cdot\text{NH}_2$  radical formation. Addition of diphenylamine, a known chain inhibitor, decelerated the thermal decomposition, supporting a radical chain reaction mechanism.

Although the molecular structure of 1-amino-2-nitroguanidine is very simple, its reactivity is surprisingly versatile. ANQ can undergo various reactions, including reduction reactions, acylation reactions, salification reactions, coordination reactions, aldimine condensation reactions, cyclization reactions, and azide reactions [439].

### 16.3 Safety Properties of Nitroaminoguanidine

Nitroaminoguanidine is sensitive to shock and friction. In the BAM impact test apparatus, the impact sensitivity was measured as 3 Nm. In the BAM friction test apparatus, the friction sensitivity was positive at 240 N pistil force. In the Picatinny tester, the impact sensitivity was 22 cm with a 2-kg weight. For comparison, the sensitivity of tetryl in the same machine was 30 cm.

### 16.4 Properties of Nitroaminoguanidinium Salts

Due to its basicity, 1-amino-3-nitroguanidine can be protonated by strong mineral acids or acidic heterocyclic compounds. The nitrate and perchlorate salts of 1-amino-3-nitroguanidine (ANQ) were synthesized by protonation of ANQ with 40% nitric acid and 60% perchloric acid, respectively [440]. Another acid, 5-nitrimino-1,4*H*-tetrazole, was used to synthesize the 1-amino-3-nitroguanidinium nitriminotetrazolate salt. The dinitramide salt of 1-amino-3-nitroguanidine was synthesized by metathesis reaction of silver dinitramide and 1-amino-3-nitroguanidinium chloride. The dinitroguanidine salt was synthesized by protonation of ANQ with 1,3-dinitroguanidine. These salts were fully characterized by single-crystal XRD; IR, Raman, and NMR spectroscopy; MS; elemental analysis; and DSC. Barium, lead, silver, and copper salts of nitroaminoguanidine are sensitive to shock and were considered as primary explosives.

Nitroaminoguanidine forms complexes with nickel(II), cobalt(II), or copper(II) nitrate, where the metal ion is surrounded by two nitrate ions, two nitroaminoguanidine molecules, and two molecules of water of hydration.

Two energetic derivatives of 1-amino-3-nitroguanidine were synthesized by introducing the furoxan moiety and the 2,4,6-trinitrophenyl moiety into the nitroguanidine frame [441]. The resulting compounds,  $C_5H_7N_7O_4$  and  $C_8H_6N_8O_8$ , were characterized by IR spectroscopy, multi-nuclear NMR, DSC, TGA, and elemental analysis. Both compounds possess good thermal stability, with the decomposition onset temperature above 453 K (180 °C).

#### 16.4.1 Nitroaminoguanidinium Nitrate

1-Amino-2-nitroguanidinium nitrate (ANGN) was synthesized and fully characterized by NMR, IR spectroscopy, DSC, MS, and elemental analysis [442]. The calculated critical temperature of thermal explosion, entropy of activation, enthalpy of activation, free energy of activation, detonation pressure, and detonation velocity were 320 K, 130.2 J mol<sup>-1</sup> K<sup>-1</sup>, 155.4 kJ/mol, 106.4 kJ/mol, 43 GPa, and 9775 m/s, respectively.

##### 16.4.1.1 Toxicity of Nitroaminoguanidinium Nitrate

*In vitro* rat hepatocyte toxicity and bacterial (*Salmonella*) genotoxicity assays were performed on 13 high-energy chemicals that are candidates for potential replacement monopropellants for hydrazine [245]. The chemicals were mostly hydrazine derivatives and amino compounds in the form of their nitrate salts. The results in hepatocytes showed a dose-dependent decrease in mitochondrial activity (MTT), an increase in lactate dehydrogenase (LDH) leakage, and depletion of GSH levels. Nitroaminoguanidinium nitrate was the least toxic of the hydrazine derivatives tested.

#### 16.4.2 Nitroaminoguanidinium Perchlorate

The chloride and perchlorate salts of 1-amino-3-nitroguanidine were synthesized by protonation of 1-amino-3-nitroguanidine with diluted hydrochloric acid and perchloric acid, respectively [443]. 5-Nitrimino-1,4*H*-tetrazole was used to synthesize the nitriminotetrazolate salt. 5-Nitrimino-1,4*H*-tetrazole was obtained by reacting 5-amino-1*H*-tetrazole with 100%  $HNO_3$ . The dinitramide salt of 1-amino-3-nitroguanidine was synthesized by metathesis reaction of silver dinitramide and 1-amino-3-nitroguanidium chloride. The dinitroguanidinate salt was synthesized by protonation of 1-amino-3-nitroguanidine with dinitroguanidine. Prior to that, dinitroguanidine was prepared by nitration of nitroguanidine in anhydrous nitric acid/ $N_2O_5$ . All compounds were fully

characterized by single-crystal XRD, vibrational spectroscopy (IR and Raman), multi-nuclear NMR spectroscopy, elemental analysis, and DSC measurements. The heats of formation of several salts were calculated and, together with the experimental XRD densities, several detonation parameters such as the detonation pressure, velocity, energy, and temperature were computed using the EXPLO5 code. The sensitivities towards impact, friction, and electrostatic discharge were tested using the BAM drop hammer, friction tester, and a small-scale electrostatic discharge test device.

### 16.5 Applications of Nitroaminoguanidine

Gun propellants with nitroaminoguanidine have lower flame temperatures, minimum smoke signature, no muzzle flash, and reduced barrel erosion in artillery guns [444].

### 16.6 Other Nitroguanidine Derivatives

A more energetic derivative of NQ is *N*-nitro-*N*-(2,2,2-trinitroethyl)guanidine (TNENG), which is a burning-rate accelerator with an activity two to three times higher than that of HMX [445].

Propellants containing 1-nitro-1-(2,2,2-trinitroethyl)guanidine, TNENG, the glycidyl azide polymer, GAP, and several energetic plasticizers were shown to exhibit burn rates much higher than conventional oxidizers. The combustion efficiency of the selected propellant for 2-in motor tests was demonstrated to be quite good.

The crystal structure of TNENG was determined by XRD for comparison with NQ, and the crystal lattice parameters were orthorhombic, space group *Pbca*,  $a = 14.611(7) \text{ \AA}$ ,  $b = 11.973(5) \text{ \AA}$ ,  $c = 11.452(5) \text{ \AA}$ ,  $V = 2003(2) \text{ \AA}^3$ ,  $Z = 8$ ,  $\rho_{\text{XRD}} = 1.758 \text{ g/cm}^3$  [446]. A hydrogen-bonded network like that present in NQ is largely responsible for the lattice cohesion of TNENG.

A series of nitroguanidine-fused bicyclic guanidinium energetic salts paired with inorganic energetic anions and mono- and ditetrazolate anions were synthesized through simple metathesis reactions of 2-iminium-5-nitriminoctahydroimidazo [4,5-d]imidazole chloride and sulfate with the corresponding silver and barium salts in aqueous solution [447]. Melting point, thermal stability, and density were measured. The structures of the nitrate salt 1 and the dinitrocyanomethanide salt 4 were confirmed by single-crystal XRD. Densities, heats of formation, predicted detonation pressures and velocities and specific impulses were calculated. All of the salts possess positive calculated heats of formation and most of them exhibited promising energetic performance that was comparable with that of TNT or RDX.

## 17 Dicyandiamide (2-Cyanoguanidine)

Dicyandiamide, also known as 2-cyanoguanidine, *N*-cyanoguanidine, DCD, CAS RN [461-58-5], is a nitrile derived from guanidine. It is a dimer of cyanamide, from which it can be prepared. Dicyandiamide is a useful intermediate in the synthesis of heterocyclic amines and energetic compounds. It can be used in gas generants as a source of nitrogen.

### 17.1 Physical Properties of Dicyandiamide (2-Cyanoguanidine)

The density of solid dicyandiamide is 1.400 g/cm<sup>3</sup>. The melting point is 482.6 K = 209.5 °C = 409.1 °F.

Adiabatic calorimetry, DSC, and TGA were used to measure thermochemical properties of dicyandiamide, such as the low-temperature heat capacity in the range 80–370 K [448]. A phase transition was found between 265 and 275 K, and the peak temperature, enthalpy, and entropy of transition were determined to be 269.5 K, 2.98 kJ/mol, and 11.07 J K<sup>-1</sup> mol<sup>-1</sup>, respectively. The high-temperature heat capacity of DCD was measured with DSC in the range 330–500 K, showing that DCD melts at 487.6 K and the enthalpy and entropy of melting were 22.96 kJ/mol and 47.68 J K<sup>-1</sup> mol<sup>-1</sup>, respectively. The TGA analysis of DCD in the range 300–850 K showed that decomposition starts at 521 K and ends at 660 K in three steps.

### 17.2 Chemical Properties of Dicyandiamide (2-Cyanoguanidine)

Dicyandiamide (2-cyanoguanidine) exists in two tautomeric forms:

Dicyandiamide (2-cyanoguanidine) can also exist in a zwitterionic form via a formal acid–base reaction among the nitrogens. Loss of ammonia from the zwitterionic form, followed by deprotonation of the remaining central nitrogen atom, gives the dicyanamide anion, [N(CN)<sub>2</sub>]<sup>-</sup>, which is widely used as the anion in ionic liquids:

2-Cyanoguanidine is a colorless solid that is soluble in water, acetone, and alcohol, but not in non-polar organic solvents. The solubility in water is 41.3 g/L. 2-Cyanoguanidine is a valuable intermediate in the synthesis of triaminoguanidinium salts and heterocyclic compounds.

The gaseous decomposition products formed by rapidly (100°/s) heating dicyandiamide under an argon atmosphere at pressures up to 6.8 MPa (1000 psi) were analyzed and found to contain  $\text{NH}_3$ ,  $\text{CO}_2$ ,  $\text{HCN}$ , and  $\text{N}_2\text{O}$  [449]. The solid products were thermally stable cyclic azines (melamine and melone). It may be these cyclic azines that are responsible for lowering the burning rate and pressure coefficient of composite propellants when dicyandiamide is added to those propellants.

The kinetics of the potassium hydroxide-catalyzed formation of melamine from dicyandiamide in diethylene glycol monoethyl ether at 383–423 K (110–150 °C) is consistent with the rate of depolymerization of dicyandiamide to cyanamide [450]. The addition of cyanamide to the reaction system caused a marked increase in the rate. The rate of formation of melamine from a mixture of dicyandiamide and cyanamide (1:1 in molar ratio) was almost identical to that of cyanamide alone. These results suggested a mechanism involving a rate-determining depolymerization of dicyandiamide to cyanamide, followed by condensation of the cyanamide produced with dicyandiamide, leading to melamine by cyclization.

Cyanamide, dicyandiamide, and the related cyclic azines (melamine, ammeline, ammelide, and cyanuric acid) were reacted in water at 373–573 K (100–300 °C) in a sealed CRES-316 tube at 275 bar for the purpose of characterizing the hydrothermolysis chemistry of cyanamide [451]. The conversion of cyanamide to dicyandiamide dominated at 373–448 K (100–175 °C). At 448–523 K (175–250 °C), when the reaction times were shorter than 15 min, the major pathway was hydrolysis of the cyanamide–dicyandiamide mixture to  $\text{CO}_2$  and  $\text{NH}_3$ . A minor pathway was cyclization to higher azines (melamine, ammeline, ammelide, and cyanuric acid). Above about 498 K (225 °C), hydrolysis of these cyclic azines to aqueous  $\text{NH}_3$  and  $\text{CO}_2$  occurred in a relative ratio which depended on the particular cyclic azine, and which, to a certain extent, increased with temperature. At 573 K (300 °C), the conversion of all compounds to  $\text{CO}_2$  and  $\text{NH}_3$  was complete in 10 min.

## 18 Guanylurea (Dicyanodiamidine) and Biguanidine (Biguanide, Guanylguanidine)

Guanylurea salts, in particular those with oxidizing anions, can be formed from cyanoguanidine with strong mineral acids such as sulfuric acid, nitric acid, or perchloric acid, and are useful propellant ingredients:

The anion  $\text{X}^-$  can be exchanged for other anions, such as azide, or nitrogen-rich organic heterocyclic compound anions. The first step in the synthesis of energetic guanylurea salts is usually the preparation of the less energetic, but more readily accessible guanylurea sulfate. Guanylurea can be formed by hydrolysis of cyanoguanidine (dicyandiamide, dicyanodiamidine)

### 18.1 Preparation of Guanylurea Sulfate

To prepare guanylurea sulfate, 16.8 g (0.2 mol) of cyanoguanidine is treated with 50 mL (0.1 mol) of 2-N sulfuric acid and kept over a hot water bath for 3–4 h. Cyanoguanidine is not soluble in water and has to be added as a slurry. The resulting solution is kept in an ice bath for 1 h, and the formed white crystals are filtered off. The rest of the filtrate can be concentrated over a hot water bath and then cooled in ice for a second crop. The resulting crystals are filtered, combined with the first crop, washed with isopropanol, and then dried in a hot-air oven. The yield is 88–90% of theory.

### 18.2 Guanylurea Nitrate and Perchlorate

Guanylurea nitrate (GUUN) and guanylurea perchlorate (GUUP) were prepared from cyanoguanidine and concentrated nitric or perchloric acid, respectively [452]. Both compounds were characterized by analytical and spectroscopic methods. Crystals of GUUP were grown from water, and its crystal structure was determined by single-crystal XRD. GUUP crystallized in the monoclinic space group  $P2_1/c$  with four molecules in the unit cell. The unit cell parameters were  $a = 8.0115(2) \text{ \AA}$ ,  $b = 9.7328(2) \text{ \AA}$ ,  $c = 9.5770(2) \text{ \AA}$ , and  $\beta = 105.89(1)^\circ$ . The heats of combustion of both com-

pounds were determined using oxygen bomb calorimetry. The predicted detonation velocity of GUUN was 5734 m/s, and the predicted detonation pressure was 10.6 GPa. Guanylurea nitrate (= dicyanodiamidinium nitrate) melts at 488 K (215 °C) with decomposition. Guanylurea nitrate,  $C_2H_7N_5O_4$ , with a nitrogen content of 42.4% N and an oxygen balance to  $CO_2$  of -33.91%, has a density of 1.54 g/cm<sup>3</sup> and is soluble in water. The salt is compatible with NC. It is non-hygroscopic and the weight gain at 30 and 90% RH was only 0.1%. GUUN had an impact sensitivity of 1.47 m (58 in) with a 2-kg weight. When heated to 373 K (100 °C) for 48 h, the weight loss was only 0.17%. In the 393 K (120 °C) vacuum stability test result, the gas evolution of a 5-g sample was only 1.54 mL of gas in 40 h.

### 18.3 Guanylurea Dinitramide (Dicyanodiamidinium Dinitramide)

*N*-Guanylurea dinitramide, GUDN,  $[H_2NC(=N^+H_2)NHCONH_2][N^-(NO_2)_2]$ , FOX-12, CAS RN [217464-38-5], an energetic material developed in Sweden by FOI (Swedish Defense Research Agency), has low sensitivity and good potential for use as a propellant ingredient, gas generant, or insensitive explosive. It is already being used in gas generators for automotive airbags, which is the first full-scale application of any dinitramide outside of Russia. FOX-12 is a new energetic oxidizer with higher energy and lower sensitivity than similar compounds used in the past. GUDN has many advantages, such as low preparation cost, low sensitivity, excellent thermal stability, non-hygroscopic properties, and good compatibility with other ingredients. *N*-Guanylurea dinitramide is under-oxidized, with an oxygen balance of -19.1%, and contains 46.9% nitrogen.

*N*-Guanylurea dinitramide is neither soluble in cold water nor hygroscopic, and has a very low sensitivity. Its synthesis, physical properties, and sensitivity (friction and drop-weight), thermal stability, and explosion temperature have been described in several publications [453–455].

#### 18.3.1 Preparation of Guanylurea Dinitramide

Guanylurea dinitramide is not very soluble in water or acids. This property has been used with advantage to separate dinitramide salts from the mixture of reaction products, by-products, and unreacted starting materials. Synthesis methods of *N*-guanylurea dinitramide (GUDN) as a new insensitive high-energetic material have been improved since it was first reported. The guanylurea ion can be formed *in situ* in the process by cyanoguanidine, which reacts and hydrolyzes within the reaction mixture. The salt can be separated by filtration and later converted to other dinitramide salts.

A simple method for converting ADN or KDN into guanidinium dinitramide or guanylurea dinitramide (= dicyanodiamidinium dinitramide) by metathetical reaction is described in [456–460]. This is done by mixing a concentrated aqueous solution of ADN with a concentrated aqueous solution of an organic ammonium salt, whose anion is either  $\text{OH}^-$  or  $\text{CO}_3^{2-}$ , which is capable of taking up a proton from the ammonium ion of ADN and forming a substituted ammonium salt. Ammonia and possibly carbon dioxide are driven off from the solution, as well as a certain amount of water to maintain a concentrated solution. The organic dinitramide salt is then precipitated by cooling the solution, and recrystallized if needed. More specifically, for preparation of GUDN in small quantities, 30.2 g (0.1 mol) guanylurea sulfate is dissolved in 50 mL of water with slight warming and stirring and cooled to room temperature. 24.8 g ADN (0.2 mol) is dissolved in 10 mL of water and added to the above solution in portions, whereupon a precipitate of fine white crystals is formed. The precipitate is filtered, washed several times with cold water, and dried under vacuum for an hour. The yield is 90–95% of theory.

FOX-12, (*N*-guanylurea dinitramide), can be synthesized by reaction of ammonium dinitramide and dicyandiamide [461]. Its structure was identified by IR and UV spectra, and some properties such as friction sensitivity, impact sensitivity, and hygroscopicity were determined.

*N*-guanylurea dinitramide can be synthesized from *N*-guanylurea hydrochloride as a starting reactant by hydrolysis and double decomposition reaction, and the overall yield of GUDN can be as high as 79% [462]. The density of GUDN made by this method was  $1.755\text{ g/cm}^3$ . The friction sensitivity of GUDN was 2.45 MPa applied to a 20-mg sample at 66 °C. The drop-weight impact sensitivity  $H_{50}$  was 197 cm when impacted with a 2-kg mass. GUDN has low sensitivity, good thermal stability, and is non-hygroscopic. The results obtained by DSC showed that GUDN is compatible with common energetic materials such as HMX and RDX, and GUDN can be used in double-base propellants.

The production of GUDN has now been scaled up and FOX-12 is available in industrial quantities for evaluation purposes [463]. Performance was evaluated by detonation velocity and cylinder expansion measurements. The sensitivity was evaluated by large-scale gap tests. Three different explosives were tested: melt cast GUNTOL (50/50 mass-% FOX-12/TNT), GUNTONL1 (42.5/42.5/15 mass-% FOX-12/TNT/Al-H2), and GUNTONL2 (42.5/42.5/15 mass-% FOX-12/TNT/Al-A100).

The GUDN synthesis process involves nitration of the ammonium salt of sulfamic acid with concentrated  $\text{HNO}_3/\text{H}_2\text{SO}_4$  at 253 to 223 K (–20 to –50 °C) and further treatment with an aqueous suspension of guanylurea sulfate to obtain GUDN as a white crystalline solid in 50% yield [464]. A systematic study with variation of different parameters such as the molar ratio of the nitrating mixture, conditioning time, and temperature was carried out in order to optimize the process parameters and obtain products in higher yield and with improved purity.

*N*-Guanylurea dinitramide can be recrystallized from dimethyl sulfoxide or *N*-methyl pyrrolidone. The enthalpies of dissolution and the kinetics of dissolution were determined by microcalorimetry [465, 466].

### 18.3.2 Physical Properties of Guanylurea Dinitramide

*N*-Guanylurea dinitramide forms pale yellow crystals with a melting point of 487 K (214 °C dec.), but they usually decompose before melting. Its crystal density is 1.755 g/cm<sup>3</sup>. The molecular mass is 209.12 g/mol. The water solubility of GUDN is 5g/L (at 293 K = 20 °C).

The properties of *N*-guanylurea dinitramide (FOX-12) have been studied [467]. FOX-12 is soluble in cold water. It has a crystal density of 1.755 g/cm<sup>3</sup>, a heat of combustion of 1484 kJ/mol, a temperature of decomposition of 491.56 K (218.41 °C), low sensitivity, and good thermal stability. FOX-12 can be mixed with common energetic materials, such as HMX, RDX, etc.

Physical and safety properties of *N*-guanylurea dinitramide are summarized in Table 34.

**Table 34:** Physical and safety properties of *N*-guanylurea dinitramide.

| Property                                   | Method                                          |                             | References |

Data source: [459]

The Raman spectrum of *N*-guanylurea dinitramide shows the lines typical for both the organic cation and the dinitramide anions (Figure 44).

**Figure 44:** FT Raman spectrum of *N*-guanylurea dinitramide. (Republished and modified from [453], with permission from ©2002 Elsevier; permission conveyed through Copyright Clearance Center Inc.)

The FT-Raman spectrum presented here was measured with an excitation wavelength of 1064  $\mu\text{m}$  and the resolution was 4  $\text{cm}^{-1}$ . The conclusion from this FT-Raman spectrum is that FT-Raman gives sharper peaks and is easier to interpret than the corresponding IR spectra.

#### 18.3.2.1 Thermodynamic Properties of Guanylurea Dinitramide

The constant-volume combustion energy, enthalpy of solution in ethyl acetate, and kinetic behavior of the exothermic decomposition reaction of GUDN were determined by a precise rotating bomb calorimeter, a Calvet microcalorimeter, and DSC, respectively [469]. See Table 36.

**Table 36:** Thermodynamic properties of *N*-guanylurea dinitramide.

| Property                                       | SI units                   | Other units    | References |
|------------------------------------------------|----------------------------|----------------|------------|
| Constant-volume energy of combustion, 298.15 K | $-7068.64 \pm 2.37$ J/g    | -1689 cal/g    | [469]      |
| Heat of combustion                             | 1484 kJ/mol                | 355 kcal/mol   | [467]      |
| Standard enthalpy of formation                 | $-319.76 \pm 0.58$ kJ/mol  | -76.4 kcal/mol | [469]      |
|                                                | -356 kJ/mol                | -85.1          | [18]       |
|                                                | -355.6 kJ/mol              | -85 kcal/mol   | [463]      |
| Enthalpy of solution in ethyl acetate          | $165.737 \pm 0.013$ kJ/mol | 39.6 kcal/mol  | [469]      |

### 18.3.2.2 Molecular Structure of Guanylurea Dinitramide

The molecular structure of guanylurea dinitramide consists of two-dimensional planar sheets and the only interaction between the sheets is via van der Waals forces. Guanylurea dinitramide crystallizes in orthorhombic crystals, space group  $Pna2_1$ , with crystal structure parameters of  $a = 13.660(10)$  Å,  $b = 9.3320(10)$  Å,  $c = 6.1360(10)$  Å,  $\alpha = \beta = \gamma = 90^\circ$ ,  $V = 782.5$  Å<sup>3</sup>,  $Z = 4$  and  $\rho_{\text{XRD}} = 1.775$  g/cm<sup>3</sup>. See also [470, 471].

### 18.3.3 Chemical Properties of Guanylurea Dinitramide

Guanylurea dinitramide is non-hygroscopic and compatible with most materials of construction and in contact with other energetic materials.

#### 18.3.3.1 Thermal Stability of GUDN

Samples of FOX-12 were heated from room temperature with heating rates ranging from 0.5 to 10 °C/min. [453]. FOX-12 has an onset of exotherm at 487.9 K (214.8 °C) with a heating rate of 10 °C/min. Using the ASTM method E 698–79, the activation energy was measured in a temperature interval from 473 to 498 K (200 to 225 °C). Compared to both RDX and ADN, FOX-12 has a higher activation energy (277 kJ/mol, compared to 201.5 kJ/mol for RDX), indicating a high degree of thermal stability. The increased thermal stability compared to ADN shows that the dinitramide ion can be stabilized by hydrogen bonding to appropriate cations and is not intrinsically unstable as was believed earlier. This is encouraging, as it seems likely that other low-sensitivity/high-thermal-stability dinitramide salts can be synthesized. The theoretical detonation properties were calculated, and the pressure dependence of the strand burning rate was measured.

An overlay of DSC curves of GUDN obtained with five different heating rates is shown in Figure 45. The peak maximum temperature ( $T_m$ ) for GUDN showed a regular increase as the heating rate was increased from 1 to 5 °C/min, which is in agreement with the general trend reported for similar compounds. Depending on which data reduction method is used, the activation energy for the decomposition of GUDN is 190 to 191.8 kJ/mol and the natural logarithm of the pre-exponential factor is 46 to 46.46.

**Figure 45:** Thermal decomposition of GUDN. (Reprinted and modified from [459], with permission granted by Dr. Santhosh 8-Feb-2021.)

The values of activation energy and pre-exponential factor of GUDN are higher than those for ADN or KDN and decrease in the order GUDN > KDN > ADN, which is also the trend of the decomposition temperatures of these three compounds.

The activation energy,  $E_a$ , and the pre-exponential factor,  $A$ , of the exothermic main decomposition reaction of GUDN were 220.2 kJ/mol and  $10^{21.18} \text{ s}^{-1}$ , respectively [469]. Other sources gave the temperature of decomposition of GUDN as 491.56 K (218.41 °C), but it was not specified whether that was the onset of the exotherm or the peak temperature of the exotherm peak [467].

The kinetics of the exothermic decomposition reaction and the specific heat capacity of *N*-guanylurea dinitramide (GUDN) were determined by DSC in a temperature-programmed mode and microcalorimeter [472]. The kinetic parameters of the major exothermic decomposition reaction, the apparent activation energy ( $E_a$ ), pre-exponential factor ( $A$ ), self-accelerating decomposition temperature, time to maximum rate, and time to ignition under adiabatic conditions were calculated. The self-accelerating decomposition temperature was 473.95 K. The time to ignition under adiabatic conditions was 3.51 s. The results showed that under non-isothermal DSC conditions, the thermal decomposition of GUDN could be described by the empiric-order autocatalytic equation

$$\frac{d\alpha}{dt} = 10^{18.49} \exp(-195500/RT)(1-\alpha)^{0.81} + 10^{18.00} \exp(-177000/RT)\alpha^{1.29}(1-\alpha)^{0.71}$$

and the value of the critical rate of temperature rise in GUDN was 0.1236 K/h when the decomposition reaction converted into thermal explosion. See also [473].

The decomposition of *N*-guanylurea dinitramide (FOX-12) and its reaction with RDX involves complex physiochemical processes that were investigated with DSC and rapid-scan FTIR of the decomposition products [474].

The thermal stability of ADN/ guanylurea dinitramide mixtures was already discussed in *Encyclopedia of Oxidizers*, chapter “Dinitramide Oxidizers.” Guanylurea dinitramide (GUDN) has excellent thermal stability and is non-hygroscopic. The thermal decomposition of guanylurea dinitramide has been studied by non-isothermal thermogravimetry (TGA) and thermogravimetry combined with mass spectrometry (TGA-MS) [475]. A strong dependence of the activation energy  $E_a$  on the degree of conversion,  $\alpha$ , was shown, where the  $E_a$  increases steadily up to an  $\alpha$  of ~0.6, followed by a marginal increase, and reaches ~435 kJ/mol at the end of the reaction.  $E_a$  has also been determined for GUDN using Kissinger’s method. A comparison of the results from the Kissinger and the isoconversional methods showed that the activation energies from these two methods are comparable. Using the model-free isoconversional method, the isothermal conversion as a function of time at two different temperatures was computed. The evolved gases during the decomposition of GUDN were analyzed by TG-MS, which revealed the formation of ions corresponding to  $N_2$ ,  $O_2$ ,  $NH_3$ ,  $H_2O$ ,  $N_2$ ,  $NO$ , methane diimine, isocyanic acid,  $N_2O$ ,  $NO_2$ , and urea.

The thermal decomposition of GUDN is a typical autocatalytic reaction [476]. Model-based kinetics were established by simultaneous fitting of a series of non-isothermal DSC data at different heating rates, which can be described as a generalized autocatalytic model and expressed by the following:

$$\frac{d\alpha}{dt} = 2.29 \times 10^{23} \exp(-225240/RT)(1 - \alpha)^{1.76} (\alpha^{1.47} + 0.59 \exp(-18300RT))$$

The reaction model matched the experimental results, with a high correlation coefficient,  $R^2$ , of 0.9994. Based on the established kinetic model, important thermal safety indicators such as the time to conversion limit, adiabatic time to maximum rate, and self-accelerating decomposition temperature were simulated, providing an important basis concerning the thermal hazard of GUDN in practical applications.

Thermal analysis revealed the compatibility of GUDN with benchmark explosives such as RDX and TNT, with which it was intended to be co-melted and co-cast in melt-cast explosive formulations [477]. GUDN was evaluated as a possible replacement for RDX/TNT-based aluminized and non-aluminized melt-cast explosive formulations. The thermal properties of the composition as well as its sensitivity to impact and friction were investigated and compared to a baseline composition based on RDX and TNT.

The isothermal decomposition of GUDN was studied by measuring gas-pressure versus time curves of the isothermal isochoric decomposition of GUDN at temperature intervals between 393 and 443 K (120 and 170 °C) [478]. An extremely long lag phase

and slow acceleration period were observed in the decomposition process of GUDN. The kinetic rate parameters of GUDN decomposition were obtained by the Arrhenius equation and a model-fitting method. An average  $E_a$  of 159.4 kJ/mol and  $\ln A$  of 34.74 s<sup>-1</sup> were obtained for the lag phase, whereas an average  $E_a$  of 125.6 kJ/mol and  $\ln A$  of 26.97 s<sup>-1</sup> were measured for the acceleration period. The time required for decomposition during long-term storage was estimated to be 9.8 years when the extent of reaction reached 0.1% at ambient temperature (298 K = 25 °C). The residue was analyzed by FTIR, gases were analyzed by GC, and a possible decomposition process equation was proposed.

The pyrolysis of GUDN was examined using DSC together with *in situ* microscopy and Raman spectroscopy, in order to determine the pyrolysis mechanism for this compound [479]. The experimental results showed that the thermal behavior of GUDN depended on the heating rate and on the presence of a condensed phase prior to a sharp exotherm at the highest heating rate. During pyrolysis of GUDN, guanidium nitrate (GN) and cyanuric acid were formed by solid-phase reactions that were associated with this exotherm, and molten GN formation promoted the exothermic reaction.

#### 18.3.4 Burning Rate of GUDN

The logarithm of the burning rate as a function of pressure showed a linear increase with pressure (Figure 46). The burning rate exponent,  $n$ , for FOX-12 was found to be

**Figure 46:** Burning rate of *N*-guanyllurea dinitramide as a function of pressure. (Reprinted and modified from [453], with permission of ©2002 Elsevier; permission conveyed through Copyright Clearance Center Inc.)

0.73, which is within the desirable range. The burning rate equation for FOX-12 is

$$r_b = 1.46p^{0.73}$$

where  $r_b$  is the burning rate in mm/s and  $p$  is the pressure in MPa. However, when mixed with inorganic oxidizers, such as perchlorates or nitrates, FOX-12 burns with a high rate and a pressure coefficient down to 0.3–0.4. See also [480].

### 18.3.5 Toxicity Hazards of GUDN

EURENCO Bofors has tested GUDN toxicity according to the European REACH regulations [481]. The test results are shown in Table 37. GUDN has received the ELINCS number 451-590-5.

**Table 37:** Toxicity and environmental effects testing of GUDN (CAS RN 217464-38-5).

| Test method                               | Test result                   |
|-------------------------------------------|-------------------------------|
| Toxicity LD50 (oral/dermal rat)           | 2000 mg/L                     |
| Toxicity to aquatic organisms LC50 (fish) | 100 mg/L                      |
| EC50 (daphnia, 48h)                       | 100 mg/L                      |
| EC50 (algae, 72h)                         | 39 mg/L                       |
| EC50                                      | 656 mg/L activated sludge, 3h |
| Acute inhalation                          | No effect                     |
| Sensitizing                               | Not sensitizing               |
| Effect on skin                            | No irritation                 |
| Effect on eyes                            | Not irritating                |
| Lipophilicity                             | Log $P_o/w$ –2.5              |
| Mutagenicity mammalian cell               | Negative                      |
| Mammalian bone marrow                     | Negative                      |
| Biodegradability COD                      | 0,1 g/g                       |
| BOD7/COD                                  | 0.5                           |

Data source: [481]

According to these tests, GUDN is considered non-carcinogenic and non-allergenic. It is not irritating, neither in contact with skin or eyes nor if inhaled.

In order to evaluate environmental pollution potential and persistence of FOX-12 if it were to be spilled accidentally in unexploded munitions, the photodegradability and biodegradability of FOX-12 were determined [482]. When dissolved in water, FOX-12 dissociated to produce the dinitramide ion moiety and guanylurea, as demonstrated by HPLC analysis. When an aqueous solution of FOX-12 was subjected to photolysis using a solar photoreactor, rapid removal of the dinitramide with concurrent formation of  $N_2O$ ,  $NO_2^-$ , and  $NO_3^-$  was observed, but the second component, guanylurea, was photostable. When FOX-12 was incubated aerobically with soil bacteria

and protected from light, the dinitramide component of FOX-12 was recalcitrant but guanylurea degraded effectively to ammonia, guanidine, and presumably  $\text{CO}_2$ . When FOX-12 was incubated with soil bacteria in the presence of light, both components of FOX-12 degraded simultaneously, giving products similar to those described above. It was recommended that FOX-12 can be effectively degraded by a joint photomicrobial process and, therefore, should not cause persistent contamination of surface waters.

### 18.3.6 Safety Properties of Guanylurea Dinitramide

The safety properties of guanylurea dinitramide have been described [468, 483]. The strand burning rate of GUDN as a pure substance is 5 mm/s at 5 MPa and 50 mm/s at 50 MPa. The pressure exponent is 0.6–0.7. The drop-weight impact sensitivity of GUDN is 49 J (maximum value according to the BAM test method). The friction sensitivity of GUDN is 353 N (maximum value according to the BAM test method). The electrostatic discharge sensitivity of GUDN is 3125 mJ (maximum value according to the test method). The critical temperature of thermal explosion of GUDN is 217.6 °C. In the large-scale gap test, GUDN had a 50% probability of detonation with 72–90 cards [463]. In the same test, Composition B required 234 cards.

Table 38 is a comparison of the sensitivity of FOX-12 to that of ADN and RDX. As can be seen, FOX-12 is less sensitive than ADN or RDX [455].

**Table 38:** Sensitivity data for GUDN in comparison to ADN and RDX.

| Compound | Explosive drop height, cm | Friction sensitivity, N m | Comments           |
|----------|---------------------------|---------------------------|--------------------|
| FOX-12   | 159                       | 350                       | Raw FOX-12         |
| ADN      | 31                        | 350                       | Unprilled material |
| RDX      | 38                        | 120                       |                    |

Data source: [453]

### 18.3.7 Applications of Guanylurea Dinitramide

The detonation velocity of GUDN is about 8210 m/s [469]. Its theoretical specific impulse when used as a rocket propellant by itself is 213.1 s. Mixtures of GUDN and HMX had a detonation velocity of 7500 m/s for a 50 : 50 mixture. In a 60-mm diameter copper tube with plane wave initiation and a 50-g Comp-B booster, the detonation velocity of FOX-12 was 7970 m/s [455].

GUDN has been evaluated as an ingredient in gas-generating compositions for airbags and seat belt tensioner systems [484, 485]. GUDN can be used in solid propellants, gas-generating agents, and as an insensitive explosive [486, 487].

### 18.4 Other Guanylurea Salts

The reaction of cyanoguanidine with hydrochloric, sulfuric, nitric, or perchloric acids yielded guanylurea chloride, sulfate, nitrate, and perchlorate. The chloride and sulfate serve as starting reactants for further syntheses to form energetic salts based on the guanylurea cation and azide, 5-nitrotetrazolate, 5-aminotetrazolate, picrate, and 5,5'-azotetrazolate anions [488]. The lower-molecular-weight salts are readily soluble in water and other polar solvents, whereas the picrate and azotetrazolate are only slightly soluble in boiling water. All materials were characterized by means of elemental analysis, MS, and vibrational (IR, Raman) and NMR ( $^1\text{H}$ ,  $^{13}\text{C}$ ,  $^{14/15}\text{N}$ , and  $^{35}\text{Cl}$ ) spectroscopy. The crystal structures were determined by low-temperature XRD. The thermal decomposition of the nitrogen-rich salts was measured by DSC, and their enthalpies of formation were calculated on the basis of the electronic energies of the ions using the MP2 method. All compounds had high thermal stabilities, as suggested by their high decomposition points ranging from 453 K (180 °C; azide) to 526 K (253 °C; picrate). All salts showed sharp onsets of decomposition without melting. They showed two sharp decomposition steps in the case of the 5,5'-azotetrazolate salts, with the only exception of the 5-aminotetrazolate salt, which had a high melting point at 425 K (152 °C) and an even higher decomposition temperature at 513 K (240 °C). The 5,5'-azotetrazolate salt showed very good long-term thermal stability. The sensitivity to shock, friction, and electrostatic discharge of all materials in the standard BAM methods was 40 J for impact and 360 N for friction sensitivity. The detonation pressures and velocities of guanylurea salts were calculated from the energies of formation using the EXPLO5 code and the results are shown in Table 39. For comparison, the detonation pressure for guanylurea dinitramide (FOX-12) is 27.6 GPa and the detonation velocity is 8308 m/s.

Guanylurea dicyanamidate is a precursor for the synthesis of graphitic carbon nitride [489]. Similar reactions were observed with guanidinium dicyanamidate [200].

## 19 Other Guanidine Derivatives

### 19.1 Biguanidine (Biguanide, Guanylguanidine)

Biguanidine, also known as biguanide, guanylguanidine, imidodicarbonimidic diamide,  $C_2H_7N_5$ ,  $HN[C(=NH)NH_2]_2$ , CAS RN [56-03-1], is a diimide and a secondary amine. It is a colorless solid that dissolves in water to give highly basic solutions. These aqueous solutions of the free base slowly hydrolyze to ammonia and urea.

#### 19.1.1 Biguanidinium Salts

Biguanidine can accept one or two protons to form biguanidinium(1+) or biguanidinium(2+) salts. The salts are sometimes also called biguanidium salts. Dry biguanidinium salts are stable in solid form and make good high-nitrogen additives to gas generants.

##### 19.1.1.1 Biguanidinium Nitrates

Biguanidinium(1+) nitrate was prepared from aqueous solutions of biguanidinium sulfate and barium nitrate, removal of the precipitated barium sulfate by filtration, and slow evaporation of the filtrate. The structures of two energetic biguanidinium salts, biguanidinium(1+) nitrate,  $[H_2NC(N=H)NHC(=NH)NH_3]^+NO_3^-$ , and biguanidinium(2+) dinitrate,  $[H_3NC(N=H)NHC(=NH)NH_3]^{2+}(NO_3^-)_2$ , have been derived from XRD data collected at 193 K [490]. The mono- and diprotonated biguanidinium nitrates are dense organic materials with efficient packing of planar anions and biplanar (twisted) cations connected by multiple hydrogen bonds. The experimental densities were  $1.62\text{ g/cm}^3$  at 193 K and  $1.59\text{ g/cm}^3$  at 298 K for the biguanidinium(1+) nitrate and  $1.75\text{ g/cm}^3$  at 193 K and  $1.73\text{ g/cm}^3$  at 298 K for the biguanidinium(2+) dinitrate salt, which agreed well with theoretical predictions. Both salts are denser than the comparable DAGN and TAGN salts. The crystal structure of biguanidinium(1+) nitrate was monoclinic with space group  $P2_1/n$ , and the cell parameters were  $a = 6.959(1)\text{ \AA}$ ,  $b = 10.778(2)\text{ \AA}$ ,  $c = 9.489(2)\text{ \AA}$ ,  $\beta = 109.28(2)^\circ$ ,  $V = 671.8(4)\text{ \AA}^3$ ,  $Z = 4$ . The crystal structure of biguanidinium(2+) dinitrate was orthorhombic with space group  $Pca2_1$ , and cell parameters were  $a = 14.0232(8)\text{ \AA}$ ,  $b = 6.8842(5)\text{ \AA}$ ,  $c = 8.9541(5)\text{ \AA}$ ,  $V = 864.4\text{ \AA}^3$ ,  $Z = 4$ .

##### 19.1.1.2 Biguanidinium Perchlorates

Biguanidinium(1+) perchlorate can be prepared by reaction of biguanidinium sulfate with barium perchlorate. Biguanidinium(2+) diperchlorate can be prepared by treating biguanidinium(1+) perchlorate with an excess of perchloric acid. The structures of two energetic biguanidinium salts have been determined from low-temperature XRD data collected at 100 K. Biguanidinium perchlorate,  $[H_2NC(N=H)NHC(=NH)NH_3]^+ClO_4^-$ , and biguanidinium(2+) diperchlorate,  $[H_3NC(N=H)NHC(=NH)NH_3]^{2+}(ClO_4^-)_2$ , have structures characterized by twisted cations and extensive hydrogen bonding

[491]. Biguanidinium(1+) perchlorate crystallized in triclinic crystals with space group  $P\bar{1}$ , and the cell parameters were  $a = 7.409 \text{ \AA}$ ,  $b = 7.619 \text{ \AA}$ ,  $c = 9.843 \text{ \AA}$ ,  $\alpha = 82.02^\circ$ ,  $\beta = 83.20^\circ$ ,  $\gamma = 69.92^\circ$ ,  $V = 515.3 \text{ \AA}^3$ ,  $Z = 2$ ,  $\rho_{\text{XRD}} = 1.95 \text{ g/cm}^3$  at 100 K. Biguanidinium(2+) diperchlorate crystallized in triclinic crystals with space group  $P\bar{1}$ , and the cell parameters were  $a = 7.7421 \text{ \AA}$ ,  $b = 9.874 \text{ \AA}$ ,  $c = 12.267 \text{ \AA}$ ,  $\alpha = 112.75^\circ$ ,  $\beta = 91.89^\circ$ ,  $\gamma = 111.91^\circ$ ,  $V = 784.9 \text{ \AA}^3$ ,  $Z = 4$ ,  $\rho = 1.71 \text{ g/cm}^3$  at 100 K.

In the DTA/DTG, biguanidinium(1+) perchlorate starts to lose mass at 597 K (324 °C) and the mass loss rate maxes at 611 K (338 °C) [492]. Time-/temperature-resolved mass spectra of the decomposition products showed similarity with the mass spectra of melamine, in particular with the peak at  $m/z = 126$  which corresponds to a melamine radical ion ( $[\text{C}_3\text{N}_6\text{H}_6]^+$ ). See also [199].

### 19.1.1.3 Biguanidinium Dinitramides

Biguanidinium(1+) mono-dinitramide crystallizes in triclinic crystals, space group  $P1$ , with  $a = 4.3686(4)$ ,  $b = 9.404(2)$ ,  $c = 10.742(1) \text{ \AA}$ ,  $\alpha = 83.54(1)^\circ$ ,  $\beta = 80.386(9)^\circ$ ,  $\gamma = 79.93(1)^\circ$ ,  $V = 426.8(1) \text{ \AA}^3$ ,  $Z = 2$ ,  $D_x = 1.62 \text{ g/cm}^3$  [493]. Biguanidinium(2+) bis-dinitramide forms monoclinic crystals with a space group  $C2/c$ ,  $a = 11.892(2) \text{ \AA}$ ,  $b = 8.131(1) \text{ \AA}$ ,  $c = 13.038(2) \text{ \AA}$ ,  $\beta = 115.79(1)^\circ$ ,  $V = 1135.1(3) \text{ \AA}^3$ ,  $Z = 4$ ,  $D_x = 1.84 \text{ g/cm}^3$ , m.p. 399–402 K. Biguanidinium(2+) bis-dinitramide also forms a monohydrate with a distinctly different crystal structure, forming orthorhombic crystals with space group  $P2_12_12_1$ ,  $a = 6.4201(6)$ ,  $b = 13.408(1)$ ,  $c = 14.584(2) \text{ \AA}$ ,  $V = 1255.4(4) \text{ \AA}^3$ ,  $Z = 4$ ,  $D_x = 1.76 \text{ g/cm}^3$ . All three structures are characterized by extensive hydrogen bonding. All the biguanidinium H atoms participate in hydrogen bonds, with an H–X (X = N, O) contact distance of less than 2.5 Å. The dinitramide anion has a surprisingly variable and asymmetric structure. The two halves of the anion are twisted with respect to each other; however, the twist varies from 5.1 to 28.9°, depending on the environment. Further, the two ends of the anion have significantly different geometries, e.g., the “equivalent” N–N bond lengths differ by up to 0.045 Å.

The electron density and hydrogen bonding in biguanidinium(1+) dinitramide and biguanidinium(2+) bis-dinitramide crystals (space groups  $P\bar{1}$  and  $C2/c$ ) have been determined from low-temperature (90 K) XRD experiments [494]. The kinetic, potential, and electronic energy distributions were calculated from the experimental electron density using DFT functionals for biguanidinium dinitramide and biguanidinium bis-dinitramide [495]. The spatial distribution of the electronic energy density was shown to be a useful descriptor of the chemical bonding and inter-molecular interactions in these molecules.

The crystal structures of biguanidinium(1+) dinitramide and biguanidinium(2+) bis-dinitramide crystals have been determined at several temperatures in the range of 85–298 K using single-crystal XRD techniques [496]. The thermal expansion was strongly anisotropic.

Single crystals of biguanidinium dinitramide undergo photolysis at low temperature, releasing free radicals which can be tracked by EPR [497].

## 19.2 Guanyl Azide

Guanyl azide nitrate was first prepared in 1892, so chemists should have had ample time to examine it, but it remains poorly characterized. Guanyl azide is formed by reaction of aminoguanidine with nitrous acid in strongly acidic solutions [228]:

Guanyl azide is a high-nitrogen compound that forms salts with strong mineral acids like nitric acid or dinitramidic acid. Guanyl azide itself is not very stable. When heated, guanyl azide decomposes to cyanamide and hydrazoic acid. Guanyl azide may exist in two tautomeric forms, but they are indistinguishable. Guanyl azide is presumed to be an intermediate in the synthesis of 5-aminotetrazole. Cyclization of guanyl azide leads to aminotetrazole. The enthalpy of formation of guanyl azide nitrate, GAzN,  $\text{C}_1\text{H}_4\text{N}_6\text{O}_3$ ,  $M = 148.08 \text{ g/mol}$ , is  $+35 \text{ cal/g} = +5.183 \text{ kcal/mol} = +21.68 \text{ kJ/mol}$ . The density is  $1.500 \text{ g/cm}^3$  [124].

Guanylazide nitrate reacts with amines to form the aminium salts of 5-aminotetrazole [498]. Amines used in this reaction included cyclohexylamine, dibutylamine, and pyrrolidine.

## 19.3 Cyanoguanyl Azide

Cyanoguanyl azide was first reported in 1928, but very little work has been done on it in the interim. Cyanoguanyl azides  $\text{NC—N=C(N}_3\text{)NHR}$  with  $\text{R} = \text{H, Me, Ar}$  can be used in the synthesis of substituted tetrazoles by reacting them with amines or hydrazines [499].

## 19.4 Nitroguanyl Azide

Nitroguanyl azide can be prepared by reaction of nitroaminoguanidine with nitrous acid in strongly acidic solutions [370]:

Nitroguanyl azide forms slightly yellowish crystals melting at  $351\text{--}352 \text{ K}$  ( $78\text{--}79^\circ\text{C}$ ) with decomposition [500]. Reactions of nitroguanyl azide with amines results in formation of heterocyclic compounds like 5-nitraminotetrazoles [501]. 5-Nitraminotetrazole forms a guanidinium salt containing 66.65% N that melts at  $498\text{--}499 \text{ K}$  ( $225\text{--}226^\circ\text{C}$ ).

The IR spectra of nitroguanyl azide and numerous other high-nitrogen compounds were published in a very useful summary [126].

Nitroguanyl azide reacts with amines to form the aminium salts of 5-nitroaminotetrazole [498]. Amines used in this reaction included *n*-propylamine, aniline, cyclohexylamine, and piperidine.

## 20 Oximes

Aldoximes and ketoximes form readily by reaction of aldehydes or ketones with hydroxylamine or hydroxylammonium salts. Sometimes this reaction is used for the separation, purification, and identification of naturally occurring aldehydes and ketones. Some of the oximes are useful as solid propellant ingredients because of their high nitrogen content and favorable oxygen balance.

The structural common link between hydroxylamines (1), oximes (2), and hydroxamic acids (3) is the N—OH group:

Formally, they can all be viewed as derivatives of hydroxylamine. A very wide-ranging survey of hydroxylamines, oximes, and hydroxamic acids was published in 2009, including chapters on intrinsic features of hydroxylamines, oximes, and hydroxamic acids [502], structural analysis of hydroxylamines, oximes, and hydroxamic acids [503], and the organic thermochemistry of hydroxylamines, oximes, hydroxamic acids, and their derivatives [504].

Oximes serve as intermediates in the synthesis of oxaza heterocyclic compounds [505].

### 20.1 Dihydroxyglyoxime

Dihydroxyglyoxime, also known as dihydroxyglyoxime, ethanedihydroxamic acid, *N,N'*-dihydroxyethane diamide, *N,N'*-dihydroxyoxamide, oxaldihydroxamic acid, oxalohydroxamic acid,  $\text{C}_2\text{H}_4\text{N}_2\text{O}_4$ , DHG, CAS RN [1687-60-1], molecular mass 120.864 g/mol, contains 23.33% nitrogen,

is a nitrogen-rich compound that has been used in a number of gas generants, and has an oxygen balance of −26.7% [506, 507]. The enthalpy of formation of

dihydroxyglyoxime is  $-542.7$  kJ/mol. Dihydroxyglyoxime can be prepared by reaction of hydroxylamine hydrochloride with diethyl oxalate in ethanol aqueous solution. An improved process prepares dihydroxyglyoxime by reaction of oxalate esters with a hydroxylammonium salt in an alkaline aqueous alcoholic solution [508]. In one example, a solution of diethyl oxalate in ethanol and an aqueous NaOH solution were added to an ethanol/water solution of hydroxylammonium chloride with stirring at 293–313 K (20–40 °C). Upon completion of the reaction, the mixture was filtered and the precipitate was dissolved in water at 353 K (80 °C) and acidified with acetic acid to give dihydroxyglyoxime in 58% yield.

The structure of oxalohydroxamic acid has been investigated by XRD and spectroscopic analyses [509]. It has been shown that oxalohydroxamic acid exists in the oxamic form in the solid as well as in solution. The variable-temperature NMR studies revealed an exchange of OH and NH protons, the exchange being faster at higher temperatures. The kinetic and thermodynamic parameters such as rate constant ( $K$ ), the free energy of activation, and the energy of activation ( $E_a$ ) for the proton exchange process have been obtained. The compound crystallized in the monoclinic shape, space group  $P2_1/c$ , with  $a = 5.208$  Å,  $b = 3.864$  Å,  $c = 11.482$  Å,  $\beta = 111.45^\circ$ , and  $Z = 2$ . There is strong hydrogen bonding between the molecules, which form dimers.

Dihydroxyglyoxime (DHG) can be prepared by reaction of hydroxylammonium chloride with diethyl oxalate in ethanol aqueous solution [510]. The molecular structure of DHG was characterized by elemental analysis, IR, and single-crystal XRD. The results showed that the crystal belongs to a monoclinic system, with  $Pn$  space group and cell parameters of  $a = 0.52219(15)$  nm,  $b = 0.38737(11)$  nm,  $c = 1.0750(3)$  nm,  $\beta = 115.396(5)^\circ$ ,  $V = 0.216(11)$  nm<sup>3</sup>,  $\rho_{\text{XRD}} = 1.873$  g/cm<sup>3</sup>, and  $Z = 2$ .

The assay of dihydroxyglyoxime in gas-generator propellants can be determined by a spectrophotometric analysis method based on the red complex formed from the reaction of dihydroxyglyoxime and iron(III) [511]. The maximum absorption wavelength of the complex was at 490 nm and the molar absorptivity was  $1.38 \times 10^3$  L mol<sup>-1</sup> cm<sup>-1</sup>. The absorption was linear within the DHG content range of 0–5 mg/50 mL.

Microencapsulation of dihydroxyglyoxime can reduce its sensitivity to moisture and incompatibility with curing agents and improve bonding with a binder [512].

Just in case dihydroxyglyoxime should find more widespread distribution as an ingredient in gas generants for air bag inflation, the toxicity of dihydroxyglyoxime was investigated in animal tests with mice [513] and rats [514].

The ammonium salt of oxalohydroxamic acid,  $[\text{NH}_4^+][\text{C}_2\text{H}_3\text{N}_2\text{O}_4^-]$ ,  $M = 137.1$  g/mol, forms during decomposition of oxalohydroxamic acid [515]. The salt crystallized in the form of triclinic crystals, space group,  $P\bar{1}$ ,  $a = 3.952(1)$ ,  $b = 6.772(1)$ ,  $c = 9.993(1)$  Å,  $\alpha = 98.06(1)^\circ$ ,  $\beta = 89.96(1)^\circ$ ,  $\gamma = 106.96(1)^\circ$ ,  $V = 253.06$  Å<sup>3</sup>,  $Z = 2$ ,  $\rho_m = 1.805$  g/cm<sup>3</sup>,  $D_{\text{XRD}} = 1.798$  g/cm<sup>3</sup>. Only one hydroxyl hydrogen is associated with each molecule.

**Table 40:** Physico-chemical and thermodynamic properties of DGH and its onium salts.

| Substance abbreviated name | Gross formula                                               | Melting point |         | Density                    |         | Enthalpy of formation |         | Molecular mass | Oxygen balance |      | Nitrogen content | Adiabatic flame temperature <sup>a</sup> |   |

<sup>a</sup> Calculated for  $P = 10.13 \text{ MPa} = 100 \text{ atm}$ 

Data source: [516]

Salts of oxaldihydroxamic acid with ammonia (A-DGH), hydrazine (H-DGH), or hydroxylamine (Ha-DGH) are capable of self-sustained burning in a wide range of pressures, producing low-temperature gaseous products [516, 517]. Properties of oxaldihydroxamic acid and three salts of oxaldihydroxamic acid are summarized in Table 40. Burning rates and pressure exponents of DGH and the salts by themselves as well as of propellants formulated with these ingredients were measured, and are reported in this publication.

## 20.2 Diaminoglyoxime

Diaminoglyoxime; 2-amino-*N'*-hydroxy-prop-2-enamidine, hydroxylamine;  $C_2H_6O_2N_4$ , DAG, is an intermediate in the synthesis of diaminofurazan (DAF) and can be used as a ballistic modifier in solid propellants. Dehydration and ring closure of diaminoglyoxime leads to the formation of diaminofurazan:

The gaseous decomposition products formed by rapidly ( $100^\circ/\text{s}$ ) heating DAG or DAF under an argon atmosphere at pressures up to 6.8 MPa (1000 psi) were analyzed and found to contain  $NH_3$ ,  $CO_2$ ,  $HCN$ , and  $N_2O$  [449]. The solid products were thermally stable cyclic azines (melamine and melone). It may be these cyclic azines that are responsible for lowering the burning rate and pressure coefficient of composite propellants when DAG or DAF are added to those propellants. See also [518].

Differential scanning calorimetry (DSC) and simultaneous thermal analysis (DTA-TGA) revealed that DAG decomposed in two stages [519]. Kinetics of the initial stage of thermal decomposition of DAG evaluated from TG data gave an activation energy of 153 kJ/mol. The high-temperature FTIR spectra of DAG decomposition products suggested preferential cleavage of  $N-O$  and  $C-NH_2$  during decomposition. Mass spectral data also suggested the possibility of similar processes.

Diaminoglyoxime can be prepared by adding glyoxal and hydroxylamine hydrochloride into a cooled solution of sodium hydroxide in water [520]. The material was characterized by using single-crystal XRD, elemental analysis and FTIR. The crystal structure was monoclinic, space group  $P2_1$ , with the cell parameters:  $a = 0.6763(8)$  nm,  $b = 0.3578(4)$  nm,  $c = 0.9658(12)$  nm,  $\beta = 90.78(2)^\circ$ ,  $V = 0.2338(5)$  nm<sup>3</sup>,

$Z = 2$ ,  $\rho_{\text{XRD}} = 1.678 \text{ g/cm}^3$ . DSC techniques with a heating rate of  $10^\circ\text{C/min}$  showed that DAG melted at  $476.6 \text{ K}$  ( $203.5^\circ\text{C}$ ). The thermal decomposition occurred in two steps at  $482\text{--}485 \text{ K}$  ( $209\text{--}212^\circ\text{C}$ ) and  $485\text{--}513 \text{ K}$  ( $212\text{--}240^\circ\text{C}$ ), and decomposition was complete at  $513 \text{ K}$  ( $240^\circ\text{C}$ ).

The thermal stability of DAF and DAG was determined by DSC and TGA-DTA [521]. The thermal degradation of DAF and DAG occurred in the temperature ranges of  $503\text{--}548 \text{ K}$  ( $230\text{--}275^\circ\text{C}$ ) and  $453\text{--}503 \text{ K}$  ( $180\text{--}230^\circ\text{C}$ ), respectively. The thermal decomposition of DAG started simultaneously with its melting. The influence of heating rate ( $5, 10, 15$ , and  $20^\circ\text{C/min}$ ) on DSC behavior showed that as the heating rate was increased, decomposition temperatures of the compounds were also increased. Based on the values of activation energy, the thermal stability of DAF was better than that of DAG.

### 20.3 Azobisformamidine Derivatives

Azobisformamidine, azodicarboxamidine, E-1,2-diazenedicarboximidamide, 1,2-diazenedicarboximidamide, *N*-(carbamidimidoylimino)guanidine, 1-carbamimidoyliminoguanidine,  $\text{C}_2\text{H}_6\text{N}_6$ , CAS RN [2625-66-3], CAS RN [6272-66-8], and its salts with oxidizing acids are useful high-nitrogen compounds and have been proposed as ingredients in gas generants for airbag inflators.

With a molecular mass of  $114.12 \text{ g/mol}$ , the nitrogen content of the free base is  $73.65\% \text{ N}$ . When protonated (singly or doubly), the positive charge is not fixed in one location, but it can move among several tautomeric forms of the ion, which helps to stabilize the compound. Azo-bis-nitroformamidine exists as the nitrimino tautomer. In this configuration it undergoes Diels-Alder additions with dienes, yielding complex heterocycles.

Azobisformamidinium(2+) dinitrate (azodicarbamidine dinitrate,  $\text{C}_2\text{H}_8\text{N}_8\text{O}_6$ ) forms yellow platelets when recrystallized from warm water, but when heated to  $453\text{--}457 \text{ K}$  ( $180\text{--}184^\circ\text{C}$ ), it explodes without melting. It can be prepared by treating a nitric acid solution of aminoguanidinium nitrate with an aqueous  $\text{KMnO}_4$  solution. The picrate salt of this base is also explosive. The IR spectrum of azobisformamidinium(2+) dinitrate shows absorption bands typical for  $=\text{NH}$  bonds and nitrate ions (Figure 47). See also [74].

**Figure 47:** IR spectrum of azobisformamidinium(2+) dinitrate (Reproduced and modified from [125], with permission from Levering Estate.)

A clean method for the preparation of azobisformamidinium(2+) dinitrate by oxidation with nitric acid instead of potassium permanganate is described in the following patent: Azodiformamidine dinitrate can be prepared by placing 10 g of aminoguanidinium nitrate (AGN) into a 400-mL glass beaker with 25 mL water, forming a slurry of AGN/water. A dispersion was formed by slowly pouring 150 mL of reagent-grade nitric acid (70%) into the AGN/water slurry while stirring. A 10-degree temperature rise occurred as the acid was first added, but the temperature came back down with continued addition of acid. The dispersion was then heated to 328–338 K (55–65 °C), with moderate stirring on a hot plate. This caused any remaining AGN to go into solution. Heating was continued at 328–338 K (55–65 °C), during which time the solution went through a color transition from a white color to a straw color to an intensely bright yellow color. For safety reasons, the reaction temperature should be limited to below 338 K (65 °C). The beaker was then placed in an ice bath to cool down the contents. A yellow precipitate appeared as the temperature dropped below 285 K (+12 °C). After the reaction mixture was held in the ice bath at about 273–278 K (0–5 °C), the yellow precipitate was vacuum filtered and washed with several rinses of distilled water. The precipitate was then washed several times with ethanol and dried at 335 K (62 °C). The procedure can also be started with aminoguanidinium bicarbonate, but more nitric acid must be used. The use of this azodiformamidine dinitrate in airbag inflators has been patented [522].
